Long columns fail by buckling at a load less than the elastic limit of the material. **Buckling** is the sudden collapse of a long column at or above the

perpendicular to AB, giving F'. Then $E'F'$ is the modified width. Similarly, KH becomes $K'H'$. The new area A' is evaluated with a planimeter.

VALUES OF A'. Rectangle (height $= h$, width $= b$): $A' = bd[1 + (h/r)^2/12 + (h/r)^4/80 + \cdots]$. Circle (radius $= R$): $A' = 2\pi r[r - \sqrt{r^2 - R^2}]$. Any section: $A' = \Sigma\{[1 - (y/r) + (y^2/r^2) - (y^3/r^3) + (y^4/r^4) - \text{etc.}]\,dA\}$. Symmetrical sections: $A' = A + (I/r^2) + (1/r^4)\Sigma(y^4da) + \text{etc.}$, where I is the moment of inertia of the section about the axis from which y is measured.

Example—Stress in Hooks (Fig. 85). The central horizontal section AB is a trapezoid; area $=$ 9.855 sq in. Radius of curvature $r = 2.5 + 1.843 = 4.343$ in. Eccentricity of load $= 4.343$ in. $A' = 10.673$ sq in. $y' = 0.33$ in. $M = 20{,}000 \times 4.343$. Substituting in the above equations,

$$S_1 = \frac{20{,}000 \times 4.343}{4.343 \times 0.818}\left(\frac{4.343}{2.5} - \frac{10.673}{9.855}\right) + \frac{20{,}000}{9.855} = 17{,}700 \text{ lb per sq in. tension.}$$

$$S_1 = \frac{20{,}000 \times 4.343}{4.343 \times 0.818}\left(\frac{10.673}{9.855} - \frac{4.343}{7}\right) - \frac{20{,}000}{9.855} = 9120 \text{ lb per sq in. compression.}$$

By the ordinary theory (p. 460), tension at $B =$ 12,700 lb per sq in., and compression at $A =$ 13,380 lb per sq in.

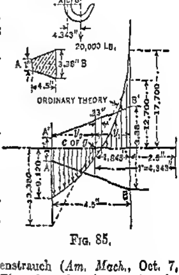

FIG. 85.

Crane Hooks. Experiments by Rautenstrauch (*Am. Mach.*, Oct. 7, 1909) yield the results given in Table 21. They show that the capacity of a hook calculated according to the ordinary theory is in excess of its real strength. See also p. 998.

Table 21. Elastic Limit of Crane Hooks

A = area, sq in. I = moment of inertia. l = distance from load line to gravity axis, in. y = distance from inner fiber to gravity axis, in.

Nominal capacity, tons	Material	Cross section dimensions				Load on hook at elastic limit, lb	Elastic limit determined on specimen cut from hook, lb per sq in.	Max unit stress by ordinary theory, lb per sq in.

length of the vertical projection; and (3) that shearing forces may be neglected. To take account of end conditions, Euler's formula includes a coefficient n.

$$P = n\pi^2EI/l^2$$

Table 16. Strength of Round-ended Columns According to Euler's Formula

P = allowable load, lb. l = length of column, in. b = smallest dimension of a rectangular section, in. d = diameter of a circular section, in. r = least radius of gyration of section.

Material	Cast iron	Wrought iron	Low-carbon steel	Medium-carbon steel
Ultimate compressive strength, lb per sq in.	107,000	53,400	62,600	89,000
Allowable compressive stress, lb per sq in. (maximum)	7,100	15,400	17,000	20,000
Modulus of elasticity	14,200,000	28,400,000	30,600,000	31,300,000
Factor of safety	8	5	5	5
Smallest I allowable at worst section, in.^{4}	$\frac{Pl^2}{17{,}500{,}000}$	$\frac{Pl^2}{56{,}000{,}000}$	$\frac{Pl^2}{60{,}300{,}000}$	$\frac{Pl^2}{61{,}700{,}000}$
Limit of ratio, $l/r >$	50.0	60.6	59.4	55.6
Rectangle ($r = b\sqrt{1/12}$), $l/b >$	14.4	17.5	17.2	16.0
Circle ($r = \frac{1}{4}d$), $l/d >$	12.5	15.2	14.9	13.9
Circular ring of small thickness ($r = d\sqrt{1/8}$), $l/d >$	17.6	21.4	21.1	19.7

Values of n: both ends rounded, $n = 1$; both ends fixed, $n = 4$; one rounded, one fixed, $n = 2$; one end fixed, one end free $n = \frac{1}{4}$. These values are theoretical. Experiments by Kirsch (*Z.V.d.I.*, 1905, p. 907) show that when $l/r = 100$ the relation of the first three coefficients, instead of being 1:4:2, is 1:1.13:1.05, and when $l/r = 200$, it is 1:3.0:1.78 in the case of wrought-iron bars 20 mm (0.79 in.) thick.

Euler's formula is proved to be reliable for long columns that fail by buckling within the elastic limit by Tetmajer's experiments (*Z.V.d.I.*, 1896, p. 1404). The value of the ratio (l/r) at which failure of round-ended columns by buckling occurred was as follows: wrought iron, 112; soft steel, 105; medium steel, 90; cast iron, 80; wood, 100. Table 16, for columns with rounded ends ($n = 1$), is based on the Euler formula.

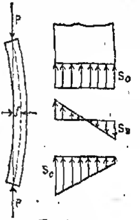

Fig. 79.

Short Columns

Rankine's formula applies to short columns, which fail under the stress S_c (Fig. 79), this stress being the sum of (1) the stress S_0, a uniform compression due to P acting as an axial load, and (2) S_B in the outer fiber due to moment M of P acting with a lever arm f around the gravity axis of the section. $S_0 = P/A$ and $S_B = Mc/I = Pfc/Ar^2$; $P = S_cA/[1 + (fc/r^2)]$, where r is the radius of gyration and c the distance from the outer fiber to the gravity axis. Here f is unknown and is replaced by Kl^2/c, giving Rankine's formula

$$P = S_cA/[1 + K(l^2/r^2)]$$

This is largely used in design. Values of K have been derived experimentally, and those recommended by Merriman are given in Table 17. Rankine's formula is to be used for values of $l/r = 20$ to 120. The value of S_c should

arch theory: $\Delta x = -K\int Myds/EI$, $\Delta y = K\int Mxds/EI$, and $\Delta\theta = K\int Mds/EI$ where the constant K is introduced to correct for the increased flexibility of a curved pipe, and where the integration is over the entire length of pipe between supports. In Table 1 are given equations derived by this method for moment and thrust at one reaction point for pipes in one plane that are fully fixed, hinged at both ends, hinged at one end and fixed at the other, or partly fixed. If the reactions at one end of the pipe are known, the moment distribution in the entire pipe then can be obtained by simple statics.

Since an initially curved pipe is more flexible than indicated by its moment of inertia, the constant K is introduced. Its value may be taken from Fig. 3, or computed from the equation given on page 499. $K = 1$ for all straight pipe sections since they act according to the simple flexure theory.

Table 1. General Equations for Pipe Lines in One Plane

Unsymmetrical	Symmetrical about y-axis
Both ends fully fixed:	
$M_0 = \dfrac{EI\Delta x(CF - AB) + EI\Delta y(BF - AG)}{2ABF + CGH - B^2H - A^2G - CF^2}$	$M_0 = \dfrac{EI\Delta xF}{GH - F^2}$
$F_x = \dfrac{EI\Delta x(CH - A^2) + EI\Delta y(BH - AF)}{2ABF + CGH - B^2H - A^2G - CF^2}$	$F_x = \dfrac{EI\Delta xH}{GH - F^2}$
$F_y = \dfrac{EI\Delta x(BH - AF) + EI\Delta y(GH - F^2)}{2ABF + CGH - B^2H - A^2G - CF^2}$	$F_y = 0$
$\Delta\theta = 0$	$\Delta\theta = 0$
Both ends hinged:	
$M_0 = 0$	$M_0 = 0$
$F_x = \dfrac{EI\Delta xC + EI\Delta yB}{CG - B^2}$	$F_x = \dfrac{EI\Delta x}{G}$
$F_y = \dfrac{EI\Delta xB + EI\Delta yG}{CG - B^2}$	$F_y = 0$
$\Delta\theta = \dfrac{\Delta x(AB - CF) + \Delta y(AG - BF)}{CG - B^2}$	$\Delta\theta = \dfrac{-\Delta xF}{G}$
Origin end only hinged, other end fully fixed	
$M_0 = 0$	
$F_x = \dfrac{EI\Delta xC + EI\Delta yB}{CG - B^2}$	
$F_y = \dfrac{EI\Delta xB + EI\Delta yG}{CG - B^2}$	
$\Delta\theta = \dfrac{\Delta x(AB - CF) + \Delta y(AG - BF)}{CG - B^2}$	
In general for any specific rotation $\Delta\theta$ and movement Δx and Δy:	
$M_0 = \dfrac{EI\Delta x(CF - AB) + EI\Delta y(BF - AG) + EI\Delta\theta(CG - B^2)}{2ABF + CGH - A^2G - CF^2 - B^2H}$	
$F_x = \dfrac{EI\Delta x(CH - A^2) + EI\Delta y(BH - AF) + EI\Delta\theta(CF - AB)}{2ABF + CGH - A^2G - CF^2 - B^2H}$	
$F_y = \dfrac{EI\Delta x(BH - AF) + EI\Delta y(GH - F^2) + EI\Delta\theta(BF - AG)}{2ABF + CGH - A^2G - CF^2 - B^2H}$	

In Fig. 3 are given the flexure constants K, α, β, and γ for initially curved pipes as functions of the quantity $\lambda = tR/r^2$. The flexure constants are derived from the equations

Table 20. Allowable Unit Stresses (Lb per Sq In.) on Steel Columns According to Various Formulas

Table 20 gives the allowable unit stresses for **steel columns** as deduced from the American Bridge Co.'s formula and also as deduced from the American Railway Engineering Assn. formula (A.R.E. Assn.); the Gordon formula, and the formulas from the building codes of the cities of Chicago, New York, Philadelphia, and Boston.

For tables of structural-steel columns and steel-pipe columns, see steel manufacturers' publications or handbooks.

For columns carrying traveling machinery, cranes, etc., add 25 percent to the live load to allow for impact and vibration.

W. H. Burr's tests on **cast-iron columns** at Phoenixville (*Eng. News*, June 30, 1898) gave a wide range of results. The *average* **ultimate strength** (in pounds per square inch) for round columns is expressed by $P/A = 30{,}500 - 165(l/d)$, where d and l are expressed in the same units. A large factor of safety, 4, must be used with cast-iron columns. Maximum slenderness ratio is 70.

COMBINED STRESSES

Combined flexure and torsion arise when a twisted shaft is bent by belts or other forces. Elements of the shaft become helices of variable pitch. An

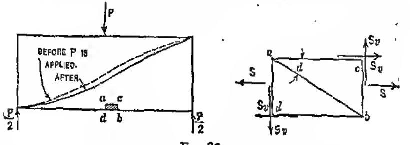

Fig. 80.

element of the surface (Fig. 80) is subjected to a flexural unit stress S due to bending moment M, and a shearing unit stress S_v, due to torsional moment

Table 2. Values of A, B, C, F, G, and H for Various Piping Elements

BENDING OF CURVED BEAMS

(From Morley, "Strength of Materials," Longmans)

Simple beam equations apply when the radius of curvature of a curved beam is large (8 to 10 times), compared to dimensions of its cross section. This is not the case in hooks, links, and rings, when some modification of formulas is necessary. Plane cross sections, normal to the axis of curvature, are assumed. The deformation (e) is proportional to the distance from the gravity axis, *but the unit deformation* (s) *is not proportional*, since the lengths of the fibers vary. The elongation of any curved fiber is evaluated, and the stress determined. The neutral axis is not at the cg, but is near the center of curvature. The stress variation is not rectilinear (Fig. 83).

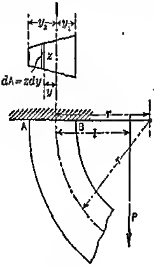

FIG. 83.

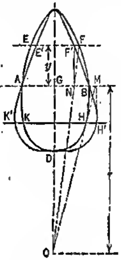

FIG. 84.

In Fig. 83, P = load; l = leverage of load about axis through cg of cross section; M = moment due to $P = Pl$; A = area of cross section; r = radius of curvature of undeformed beam from center of curvature to cg of cross section. Stress due to combination of direct load P (taken as acting at cg) and moment $M = S$, or the normal unit stress at distance y from axis through cg. The equations which follow are for pure bending, but apply with little error to ordinary bending, including shear.

$$S_1 \text{ (at } B) = \frac{M}{r(A' - A)}\left(\frac{r}{r - y_1} - \frac{A'}{A}\right) + \frac{P}{A} \text{ (tension)}$$

$$S_2 \text{ (at } A) = \frac{M}{r(A' - A)}\left(\frac{A'}{A} - \frac{r}{r + y_2}\right) - \frac{P}{A} \text{ (compression)}$$

where

$$A' = r\Sigma\left(\frac{dA}{y + r}\right)$$

The neutral axis is at a distance y' from cg, where $y' = r\left(\frac{A' - A}{A'}\right)$.

A' may be considered as a "modified" area, and is obtained graphically (Fig. 84) as follows: To find $A' = r\Sigma\left(\frac{dA}{y + r}\right)$, first find the cg of the original cross section. Lay off O so that $OG = r$. Change each width in the ratio of $r/(y + r)$. For example, draw OF intersecting AB in N. Draw NF'

Reactions and stresses are greatly influenced by **flattening** of the cross **section** of the curved portions of the pipe line.

It is recommended that **cold springing** allowances be discounted in stress calculations.

Application to Two- and Three-plane Pipe Lines. Pipe lines in more than one plane may be solved by the successive application of the preceding data, dividing the pipe line into two or more one-plane lines.

Example. The unsymmetrical pipe line of Fig. 4 has fully fixed ends From Table 2 use $K = 1$ for all sections, since only straight segments are involved,

Part of pipe	Values of integrals					
	A	B	C	F	G	H
0–1	$\frac{a^2}{2}$	0	$\frac{a^3}{3}$	0	0	a
1–2	ab	$\frac{ab^2}{2}$	a^2b	$\frac{b^2}{2}$	$\frac{b^3}{3}$	b
2–3	$\frac{c}{2}(2a + c)$	$\frac{bc}{2}(2a + c)$	$\frac{c^3}{3} + ac(a + c)$	bc	b^2c	c
Total 0–3	$\frac{a^2}{2} + ab + \frac{c}{2}(2a + c)$	$\frac{ab^2}{2} + \frac{bc}{2}(2a + c)$	$\frac{a^3}{3} + a^2b + \frac{c^3}{3} + ac(a + c)$	$\frac{b^2}{2} + bc$	$\frac{b^3}{3} + b^2c$	$a + b + c$

Upon introduction of $a = 120$ in., $b = 60$ in., and $c = 180$ in., into the preceding relations for A, B, C, F, G, H, the equations for the reactions at 0 from Table 1 become

$$M_0 = EI\Delta x(-7.1608 \times 10^{-5}) + EI\Delta y(-8.3681 \times 10^{-5})$$
$$F_x = EI\Delta x(+1.0993 \times 10^{-6}) + EI\Delta y(+3.1488 \times 10^{-7})$$
$$F_y = EI\Delta x(+3.1488 \times 10^{-7}) + EI\Delta y(+1.33717 \times 10^{-7})$$

Also it follows that

$$M_1 = M_0 + F_ya = EI\Delta x(+3.06248 \times 10^{-4}) + EI\Delta y(+7.6779 \times 10^{-5})$$
$$M_2 = M_1 - F_xb = EI\Delta x(+2.4029 \times 10^{-4}) + EI\Delta y(-1.1215 \times 10^{-4})$$
$$M_3 = M_2 + F_yc = EI\Delta x(+8.0707 \times 10^{-4}) + EI\Delta y(+1.2854 \times 10^{-4})$$

Thus the maximum moment M occurs at 3.

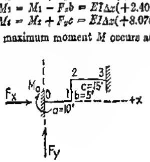

Fig. 4.

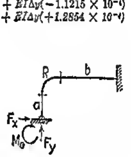

Fig. 5.—Right-angle Pipe Line.

The total maximum longitudinal fiber stress ($\alpha = .1$ for straight pipe)

$$= \frac{F_x}{2\pi rt} \pm \frac{Mr}{I}$$

There is no transverse flexure stress since all sections are straight. The maximum shearing stress is either (a) one-half of the maximum longitudinal fiber stress as given above, (b) one-half of the hoop-tension stress caused by any internal radial pressure that might exist in the pipe, or (c) one-half the difference of the maximum longitudinal

PIPE LINE FLEXURE STRESSES CAUSED BY EXPANSION OR MOVEMENT OF SUPPORTS

BY

H. V. HAWKINS AND W. H. SHIPMAN

References: Shipman, "Design of Steam Piping to Care for Expansion," *Trans. A.S.M.E.*, 1929. Wahl, "Stresses and Reactions in Expansion Pipe Bends," *Trans. A.S.M.E.*, 1927. Hovgaard, "The Elastic Deformation of Pipe Bends," *Jour. Math. Phys.*, Nov., 1926, and Oct., 1928.

Nomenclature.

M_0 = end moment at origin, in-lb.

M = max moment, in-lb.

F_x = end reaction at origin in x-direction, lb.

F_y = end reaction at origin in y-direction, lb.

S_l = $(Mr/I)\alpha$ = max unit longitudinal flexure stress, lb per sq in.

S_t = $(Mr/I)\beta$ = max unit transverse flexure stress, lb per sq in.

S_s = $(Mr/I)\gamma$ = max unit shearing stress, lb per sq in.

Δx = relative deflection of ends of pipe parallel to x-direction caused by either temperature change or support movement, or both, in.

Δy = same as Δx but parallel to y-direction, in. Note that Δx and Δy are positive if under the change in temperature the end opposite the origin tends to move in a positive x- or y-direction, respectively.

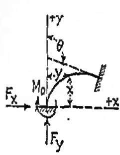

Fig. 1.

t = wall thickness of pipe, in.

r = mean radius of pipe cross section, in.

λ = constant $= tR/r^2$.

I = moment of inertia of pipe cross section about pipe center line, in[4].

E = modulus of elasticity of pipe at *actual working* temperature, lb per sq in.

K = flexibility index of pipe. $K = 1$ for all straight pipe sections, $K = (10 + 12\lambda^2)/(1 + 12\lambda^2)$ for all curved pipe sections where $\lambda > 0.335$ (see Fig. 3).

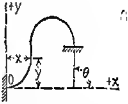

Fig. 2.

α, β, γ = ratios of actual max longitudinal flexure, transverse flexure, and shearing stresses to Mr/I for curved sections of pipe (see Fig. 3).

A, B, C, F, G, H = constants given by Table 2.

θ = angle of intersection between tangents to direction of pipe at reactions.

$\Delta\theta$ = change in θ caused by movements of supports, or by temperature change, or both, radians.

ds = an infinitesimal element of the length of the pipe.

R = radius of curvature of pipe center line.

General Discussion

Under the effect of changes in temperature of the pipe line, or of movement of support reactions (either translation or rotation), or both, the determination of stress distribution in a pipe becomes a statically indeterminate problem. In general the problem may be solved by a slight modification of the standard

fiber stress and hoop-tension stress, whichever of these three possibilities is numerically greatest.

The reactions for a right-angle pipe line (Fig. 5) may be determined from the following equations:

$$M_0 = C_1 EI\Delta x/R^2$$
$$F_x = C_2 EI\Delta x/R^3$$
$$F_y = C_3 EI\Delta x/R^3$$

In these equations, Δx is the x-component of the deflection between reaction points caused by *temperature change only*. The values of C_1, C_2, and C_3 are given in Fig. 6 for $K = 1$ and for $K = 2$. For other values of K, interpolation may be employed.

Example. With $a/R = 20$ and $b/R = 3$, the value of C_1 is 0.0192 for $K = 1$ and 0.0170 for $K = 2$. If $K = 1.75$, the interpolated values of C_1 is 0.0180. With the origin at the right-hand end (Fig. 5), C_1 is 0.248 for $K = 1$.

$$K = (10 + 12\lambda^2)/(1 + 12\lambda^2), \quad \text{when} \quad \lambda > 0.335$$
$$\alpha = \tfrac{2}{3}K\sqrt{(5 + 6\lambda^2)/18}$$
$$\beta = 18\lambda/(1 + 12\lambda^2)$$
$$\gamma = [8\lambda - 36\lambda^3 + (32\lambda^2 + \tfrac{20}{3})\sqrt{\tfrac{2}{3}\lambda^2 - \tfrac{5}{18}}]/(1 + 12\lambda^2), \quad \text{when} \quad \lambda < 0.58$$
$$= (12\lambda^2 + 18\lambda - 2)/(1 + 12\lambda^2), \quad \text{when} \quad \lambda > 0.58$$

The increased flexibility of the curved pipe is brought about by the tendency of its cross section to flatten. This flattening causes a transverse flexure stress whose maximum is S_t. Because the maximum longitudinal and maximum transverse stresses do not occur at the same point in the pipe's cross section, the resulting maximum shear is not one-half the difference of S_l and S_t; it is S_s. In the straight sections of the pipe, $\alpha = 1$, the transverse stress disappears, and $\gamma = \frac{1}{2}$. This discussion of S_s does not include the uniform transverse or longitudinal tension stresses induced by the internal pressure in the pipe; their effects should be added if appreciable.

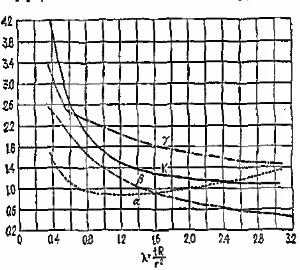

FIG. 3.—Flexure Constants for Initially Curved Pipes.

Table 2 gives values of *the constants A, B, C, F, G, and H for use* in equations listed in Table 1. The values may be used (1) for the solution of any pipe line, or (2) for the derivation of equations for standard shapes composed of straight sections and arcs of circles as in Fig. 5. Equations for shapes not given may be obtained by algebraic addition of those given. All measurements are from the left-hand end of the pipe line. Reactions and stresses are very greatly influenced by end conditions. Formulas are given to cover the extreme conditions. The following suggestions and comments should be considered when laying out a pipe line:

Avoid expansion bends, and design the entire pipe line to take care of its own expansion.

The movement of the equipment to which the ends of the pipe line are attached must be included in the Δx and Δy of the equations.

Maximum flexibility is obtained by placing **supports and anchors** so that they will not interfere with the natural movement of the pipe.

That shape is most efficient in which the **maximum length of pipe** is **working** at the maximum safe stress.

Excessive **bending moment at joints** is more likely to cause trouble than excessive stresses in pipe walls. Hence, keep pipe joints away from points of *high moment.*

The period of free vibration is

$$T = 2\pi/\omega_n = 2\pi\sqrt{W/kg} = 2\pi\sqrt{\delta_{st}/g} \tag{4}$$

It is seen that the period is the same as the period of a mathematical pendulum the length of which is equal to the static deflection of the spring under the action of the load W. This conclusion can always be used in calculating the period of free vibration of elastic systems when the static deflections are proportional to the load and the mass of the elastic portion of the system (in the above illustration the mass of the spring) can be neglected in comparison with the mass of the load. Taking, for instance, a beam with supported ends loaded at the middle, and neglecting the mass of the beam in comparison with the mass of the load W, the static deflection of the beam will be $\delta_{st} = Wl^3/48EI$ and the period of free vibration will be

$$T = 2\pi\sqrt{Wl^3/48EIg}$$

Vibrations with Damping. In practice, resisting forces are always present which cause a gradual damping of the original vibrations. These damping forces may arise from various sources such as air or fluid resistance, internal friction of the material of the vibrating body, or friction between sliding surfaces. When a body is vibrating in air or in a liquid and velocities are small, such as may exist in dashpots, the **resisting force is proportional to velocity** and the differential equation of vibration is

$$\frac{W}{g}\ddot{x} + c\dot{x} + kx = 0 \tag{5}$$

in which $c\dot{x}$ denotes the resisting force of the moving body. Using the notation

$$q^2 = \omega_n^2 - n^2, \tag{6}$$

where $n = cg/2W$, the general solution of Eq. (5) will be

$$x = e^{-nt}[(\dot{x}_0/q)\sin qt + x_0(\cos qt + (n/q)\sin qt)] \tag{7}$$

The damped vibratory motion has a period:

$$T = 2\pi/q = 2\pi/\sqrt{\omega_n^2 - n^2} \tag{8}$$

The quantity n is usually small in comparison with ω_n and the difference between q and ω_n is a small quantity of the second order. It can be assumed therefore that a small damping force does not affect the period of vibration.

The amplitude of the vibrations (7) gradually decreases with the time, due to the factor e^{-nt}, diminishing after every cycle in the ratio

$$e^{-nt}:1 \tag{9}$$

This ratio is used in experimental determination of the **coefficient of damping.**

In the case of a **constant friction** such as exists between two dry surfaces of sliding bodies under constant pressure, the period of vibration is the same as in the case of free vibrations without resisting forces [Eq. (4)]. The amplitude of vibration diminishes after each half cycle by the quantity

$$a = 2R/k \tag{10}$$

where R denotes the resisting force and k is the spring constant.

Forced Vibrations. When a periodical disturbing force $Q \sin \omega t$ is acting on the vibrating body, the differential equation of vibration will be

$$\frac{W}{g}\ddot{x} + c\dot{x} + kx = Q\sin\omega t \tag{11}$$

	$\left(\frac{\pi x}{2} + R\right) KR$	$Ay + \left(x + \frac{R}{2}\right) KR^2$	$Ax + \left(\frac{\pi R}{4} + x\right) KR^2$	$\left(\frac{\pi y}{2} + R\right) KR$	$Fy + \left(\frac{\pi R}{4} + y\right) KR^2$	$\frac{\pi KR}{2}$
		$Ay - \left(x + \frac{R}{2}\right) KR^2$		$\left(\frac{\pi y}{2} - R\right) KR$	$Fy + \left(\frac{\pi R}{4} - y\right) KR^2$	
	$\left(\frac{\pi x}{2} - R\right) KR$	$Ay - \left(x - \frac{R}{2}\right) KR^2$	$Ax + \left(\frac{\pi R}{4} - x\right) KR^2$	$\left(\frac{\pi y}{2} - R\right) KR$	$Fy + \left(\frac{\pi R}{4} - y\right) KR^2$	
	$\left(\frac{\pi x}{4} - \frac{R}{\sqrt{2}}\right) KR$	$Ay + \left[\left(1 - \frac{\sqrt{2}}{2}\right)x - \frac{R}{4}\right] KR^2$	$Ax + \left[\left(\frac{\pi}{8} + \frac{1}{4}\right)R - \frac{\sqrt{2}x}{2}\right] KR^2$	$\left[\frac{\pi y}{4} + \left(1 - \frac{\sqrt{2}}{2}\right)R\right] KR$	$Fy + \left[\left(1 - \frac{\sqrt{2}}{2}\right)y + \left(\frac{\pi}{8} - \frac{1}{4}\right)R\right] KR^2$	$\frac{\pi KR}{4}$
		$Ay - \left[\left(1 - \frac{\sqrt{2}}{2}\right)x \frac{R}{4}\right] KR^2$		$\left[\frac{\pi y}{4} - \left(1 - \frac{\sqrt{2}}{2}\right)R\right] KR$	$Fy - \left[\left(1 - \frac{\sqrt{2}}{2}\right)y - \left(\frac{\pi}{8} - \frac{1}{4}\right)R\right] KR^2$	
	$\left(\frac{\pi x}{4} + \frac{R}{\sqrt{2}}\right) KR$	$Ay + \left[\left(1 - \frac{\sqrt{2}}{2}\right)x + \frac{R}{4}\right] KR^2$	$Ax + \left[\left(\frac{\pi}{8} + \frac{1}{4}\right)R + \frac{\sqrt{2}x}{2}\right] KR^2$	$\left[\frac{\pi y}{4} + \left(1 - \frac{\sqrt{2}}{2}\right)R\right] KR$	$Fy + \left[\left(1 - \frac{\sqrt{2}}{2}\right)y + \left(\frac{\pi}{8} - \frac{1}{4}\right)R\right] KR^2$	
		$Ay - \left[\left(1 - \frac{\sqrt{2}}{2}\right)x + \frac{R}{4}\right] KR^2$		$\left[\frac{\pi y}{4} - \left(1 - \frac{\sqrt{2}}{2}\right)R\right] KR$	$Fy - \left[\left(1 - \frac{\sqrt{2}}{2}\right)y - \left(\frac{\pi}{8} - \frac{1}{4}\right)R\right] KR^2$	
	$[x(\theta_2 - \theta_1) - R(\sin\theta_2 - \sin\theta_1)] KR$	$Ay\left[x(\cos\theta_2 - \cos\theta_1) + \frac{R}{2}(\sin^2\theta_2 - \sin^2\theta_1)\right] KR^2$	$Ax - \left[x(\sin\theta_2 - \sin\theta_1) - \frac{R}{4}(\sin 2\theta_2 - \sin 2\theta_1) - \frac{R}{2}(\theta_2 - \theta_1)\right] KR^2$	$[y(\theta_2 - \theta_1) - R(\cos\theta_2 - \cos\theta_1)] KR$	$Fy - \left[y(\cos\theta_2 - \cos\theta_1) + \frac{R}{4}(\sin 2\theta_2 - \sin 2\theta_1) - \frac{R}{2}(\theta_2 - \theta_1)\right] KR^2$	$(\theta_2 - \theta_1) KR$

also very useful for an approximate calculation of the frequency of more complicated systems. Considering the arrangement of Fig. 1 and neglecting at first the mass of the spring, the kinetic energy of the system during the vibration is

$$T = W(\dot{x})^2/2g \tag{15}$$

Measuring the displacement of x from the position of equilibrium and taking into consideration that the weight W is always in balance with the initial tensile force in the spring, the increase in potential energy during the displacement x will be

$$V = kx^2/2 \tag{16}$$

Then on the basis of the principle of conservation of energy, neglecting the damping, we have

$$(W\dot{x}^2/2g) + kx^2/2 = \text{const.} \tag{17}$$

This means that during vibration the sum of the kinetic and potential energy remains constant and equal to its initial value. Assuming, for instance, that at $t = 0$ the displacement is equal to x and the initial velocity is zero, Eq. (17) becomes

$$(W\dot{x}^2/2g) + kx^2/2 = kx_0^2/2 \tag{18}$$

When, during vibration, x becomes equal to x_0, the velocity of the weight W becomes equal to zero and the energy of the system consists of the potential energy only. When x becomes equal to zero, which occurs when the load during vibration passes through its middle position, the velocity has its maximum value and the corresponding magnitude of the kinetic energy, from Eq. (18), becomes

$$W(\dot{x})^2_{max}/2g = kx_0^2/2 \tag{19}$$

This means that at this moment the total energy of the system is kinetic and equal to the potential energy which has been stored in the system during the initial displacement x_0 from the position of equilibrium. Equation (19) can be used for calculating the frequency of vibration of the system. It has been shown (p. 505) that in this case we have a simple harmonic motion, *i.e.*, it can be taken

$$x = x_0 \cos \omega_n t \text{ and } (\dot{x})_{max} = x_0\omega_n$$

Substituting in (19) we obtain

$$\omega_n^2 = kg/W$$

This coincides with the result previously obtained (p. 509).

In the foregoing consideration, the mass of the spring was neglected in comparison with the mass of the weight W. In order to determine the effect of such a simplification on the frequency of vibration, the approximate method developed by Lord Rayleigh may be employed. Assuming that the mass of the spring is small in comparison with the mass of the load W, the type of vibration will not be substantially affected by the mass of the spring and it can be assumed with sufficient accuracy that during vibration the displacement of any cross section of the spring at a distance c from the fixed end (Fig. 1) is xc/l. Let w denote the weight of the spring per unit length, then the mass of an element of the spring of the length dc will be $w\,dc/g$ and the kinetic energy of the spring itself will be

$$\frac{w}{2g}\int_0^l \left(\frac{\dot{x}c}{l}\right)^2 dc = \frac{\dot{x}^2}{2g}\left(\frac{wl}{3}\right)$$

and the energy Eq. (18) becomes

$$(W\dot{x}^2_{max}/2g) + (wl/3)\dot{x}^2_{max}/2g = kx_0^2/2 \tag{20}$$

It can be concluded from this that in order to estimate the effect of the mass of the spring on the period of natural vibration it is only necessary to add one-third of the weight of the spring to the weight W. Applying the same manner of reasoning to the case shown in Fig. 3, it can be shown that in order to take into consideration the mass of the beam in calculating the frequency of natural vibrations it is necessary to add to the weight W of the load $^{17}\!/_{35}$ of the weight of the beam. In the case of a cantilever loaded at the end by load W, a satisfactory approximation in calculating frequency will be obtained by adding to the load W, $^{33}\!/_{140}$ of the weight of the cantilever.

Non-harmonic Vibrations. In the previous discussion, it was assumed that the spring constant of the system was independent of the displacement x.

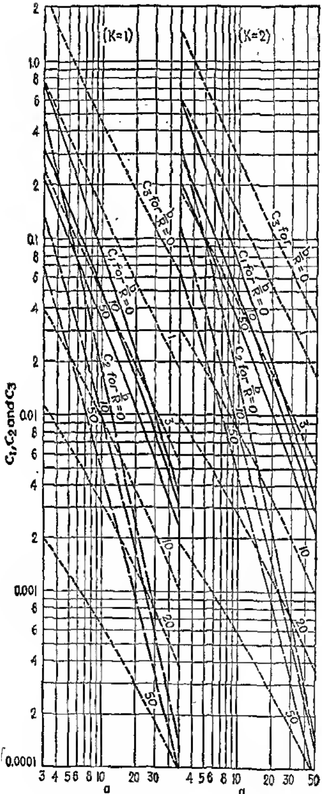

FIG. 6.—Reactions for Right-angle Pipe Lines.

distribution are always present. As a result of this, periodical disturbing forces occur which produce vibrations. In order to remove these vibrations in machines and establish quiet running conditions, balancing becomes necessary, especially in the case of large high-speed machines. Various conditions of unbalance of a rotor are shown in Fig. 6. Imagine the rotating body divided into two parts by any cross section mn. The three following typical cases of unbalance may arise:

1. The centers of gravity of both parts may be in the same axial plane and on the same side of the axis of rotation as shown in Fig. 6b. The center of gravity C of the whole body will consequently be in the same plane at a certain distance from the axis of rotation. This is called **static unbalance**, because it can be detected by a statical test. A statical balancing test consists of putting the rotor with the two ends of its shaft on absolutely-horizontal parallel rails. If the center of gravity of the whole rotor is in the axis, the rotor will be in static equilibrium in any position; if the center is off the axis, as in Fig. 6b, it will roll on the rails till the center of gravity reaches its lowest position.

2. The centers of gravity of both parts may be in the same axial plane but on opposite sides of the axis of rotation as shown in Fig. 6c and at such radial distances that the center of gravity C of the whole body will be exactly on the axis of rotation. In this case, the body will be in balance under static conditions, but during rotation a disturbing couple of centrifugal forces P will act on the rotor. This couple rotates with the body and produces vibrations in the foundation. Such a case is called **dynamic unbalance.**

3. In the most general case, the centers of gravity C_1 and C_2 may lie in different axial sections and during rotation a system of two forces formed by the centrifugal forces P and Q will act on the body, Fig. 6d. This system of forces can always be reduced to a couple acting in an axial section and a radial force, *i.e.*, static and dynamic unbalance will occur together.

In all cases, a complete balancing can be obtained by attaching to the rotor a weight in each of two cross-sectional planes arbitrarily chosen, provided the position and magnitude of the unbalance is known. For determining this unbalance, various types of **balancing machines** are used. A balancing machine represents usually an arrangement in which the effects of any unbalance in the rotor which is under test may be magnified by resonance. In the older types of balancing machines, the vibration was observed visually or recorded graphically. Sometimes the vibration was eliminated by adjustable compensating weights. In the more modern types, such as those made by the Tinius Olsen Co. of Philadelphia, electric recording is used. In the Gisholt-Westinghouse balancing machine, the entire operation has been made automatic by means of electric circuits.

Experience with large high-speed machines shows that while balancing carried out on the balancing machine in the shop may show good results, nevertheless this testing is usually done at comparatively low speed and in service, where the operating speeds are high, unbalance may still be apparent due to slight changes in mass distribution. It is therefore necessary also to check the balancing condition for normal operating speed. This test is carried out either in the shop where the rotor is placed for this purpose on rigid bearings or in the field after it is assembled in the machine. The magnitude and the location of the correction weight can then be found from measurements of the amplitudes of vibrations of the pedestal, which are recorded by a vibrometer.

VIBRATION

Notation.

W = the weight of a vibrating body.
g = acceleration due to gravity.
I = moment of inertia of an oscillating disk about the axis of oscillation.
G = modulus of elasticity in shear.
E = modulus of elasticity in tension.
ν = Poisson's ratio.
k = the spring constant, *i.e.*, the force necessary to produce a deflection of a spring equal to unity or the couple necessary to produce an angle of twist of a shaft equal to one radian.
$\delta_{st} = W/k$ = the static deflection of the spring under the action of the load W.
T = the period, *i.e.*, the time of one oscillation.
$f = 1/T$ = the frequency, *i.e.*, the number of oscillations per second.
$\omega_n = \sqrt{gk/W}$ or $\omega_n = \sqrt{k/I}$ = the number of free oscillations per 2π sec.
A = the amplitude of the vibration.
α = the phase of the vibration.
c = the coefficient of damping.
$Q \sin \omega t$ = the periodical disturbing force.
$T_1 = 2\pi/\omega$ = the period of the disturbing force.
$f_1 = 1/T_1 = \omega/2\pi$ = the frequency of the disturbing force.

$\dot{x}$ and $\ddot{x}$ are the first and second derivatives of x with respect to time, *i.e.*, are velocity and acceleration, respectively.

Free Harmonic Vibration. The simplest case of a vibrating system with one degree of freedom is shown in Fig. 1. The weight W attached to the spring has freedom to vibrate in the vertical direction, and the mass of the spring is small in comparison with the mass of the load W.

If x denotes the displacement of the oscillating load from the position of equilibrium, the differential equation of free vibration will be

$$\ddot{x} + \omega_n^2 x = 0 \tag{1}$$

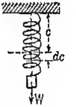

FIG. 1.

The general solution of this equation is

$$x = x_0 \cos \omega_n t + (\dot{x}_0/\omega_n) \sin \omega_n t \tag{2}$$

in which x_0 is the displacement of the body from the position of equilibrium at the initial moment ($t = 0$), and $\dot{x}_0$ is the initial velocity.

Substituting in Eq. (2),

$$x_0 = A \sin \alpha; \qquad \dot{x}_0/\omega_n = A \cos \alpha$$

we obtain

$$x = A \sin (\omega_n t + \alpha) \tag{3}$$

The unbalanced forces for various in-line engines with equal and equally spaced cylinders are shown in the table on page 511.

Engines of more cylinders are usually arranged in a V formation, with 6, 8, or 12 cylinders in each bank of the V. Since each bank is completely balanced in itself, the entire engine is also balanced for any angle between the two legs of the V. In the V-8 engine, consisting of two four-cylinder blocks of the 0-90-270-180 type crankshaft, each bank is unbalanced in primary moments. It is possible to balance this engine completely by so choosing the counterweight that the longitudinal and lateral unbalances of each individual cylinder are equal and opposite ($F_1 = -F_2$). By making the V angle 90 deg, the longitudinal forces of one block fall in line with the lateral forces of the other block, and vice versa, thus compensating each other, which ensures perfect balance.

Radial engines with master connecting rods as used in aircraft are not entirely symmetrical radially since the master rod is much heavier than the other rod. Therefore these engines labor under the same difficulty as single-cylinder engines, *i.e.*, they can be balanced in the direction of the master rod or across it, but not in both directions simultaneously. Larger radial engines with two-throw crankshafts and two stars of cylinders have the balance characteristics of two-cylinder-in-line engines.

Vibration Absorbers. The balancing of a machine can never be absolutely perfect, and there exists always a certain amount of unbalance which results in disturbing forces producing vibrations. In order to reduce the effect of disturbing forces on the foundation of a machine and to prevent the transmission of vibrations to the building, the introduction of special flexible elements between the machine and the foundation may be useful. Let W = the weight of the machine and $Q \sin \omega t$ = the impressed vertical force (Fig. 7), which is usually due to unbalance. If the machine is rigidly attached to the foundation, the entire disturbing force will be transmitted to the foundation. By introducing the flexible springs of a vibration absorber between the machine and the foundation, a substantial reduction in the force transmitted to the support can be obtained. It is only necessary to design the springs of the absorber in such a manner as to make the period T_n of natural vibration of the machine W on the springs large in comparison with the period $T = 2\pi/\omega$ of the machine. Vibration will then be reduced [see Eq. (13)] as compared with the displacements which would be produced by the disturbing force $Q \sin \omega t$ under static conditions. The forces which are transmitted to the foundation are proportional to the deflection of the springs, and therefore will be reduced in the same ratio also. Neglecting damping and taking, for instance, $T_n/T = 4$, *i.e.*, assuming that the operating speed is four times that corresponding to resonance, it will be found from Eq. (13) that the amplitude of the forced vibration is only $\frac{1}{15}$ of the statical deflection, or the force transmitted to the foundation will be reduced to $\frac{1}{15}$ of the impressed force.

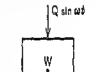

FIG. 7.

FIG. 8.

The actual design of an absorber frequently offers difficulties, principally on account of space limitation. It is difficult to have sufficient space for placing springs which will be strong enough to transmit the load to the foundation and at the same time flexible enough to make the resonance speed of the system small in comparison with the operating speed. In Fig. 8, a schematic view of a vibration absorber for a large single-phase generator is shown. In order to reduce the effect of the pulsating torque, flexible springs are introduced between the stator of the machine and the foundation. By the use of special guides, the possibility of lateral displacement of the stator is prevented and only a rotation about the 0 axis remains possible.

Let k = the torque necessary to produce a statical deformation of the springs such that the rotation of the stator about the 0 axis perpendicular to the plane of the figure is

Vibrations consist of two parts, free damped vibrations such as are represented by Eq. (5) and forced vibrations. The free vibrations will be damped out, and the forced vibrations alone are of practical importance. The general expression for forced vibrations is

$$x = A \sin (\omega t - \alpha) \tag{12}$$

where the amplitude of vibration and the phase are given by the following equations:

$$A = (Q/k)\left(1/\sqrt{\left(1 - \frac{\omega^2}{\omega_n^2}\right)^2 + c^2\omega^2/k^2}\right) \tag{13}$$

$$\tan \alpha = c\omega/k(1 - \omega^2/\omega_n^2) \tag{14}$$

The first factor on the right side of Eq. (13) is the deflection calculated statically, *i.e.*, by division of the maximum magnitude of the disturbing force by the spring constant. The second factor is due to dynamical conditions and is called the **magnification factor.** In Fig. 2 the magnification factor is represented as a function of the ratio ω/ω_n, and for various values of the constant c, which is the coefficient of damping.

When the disturbing force has a very low frequency as compared with the frequency of the natural vibrations of the system, the ratio ω^2/ω_n^2 is small and the magnification factor approaches unity. Another extreme case occurs when the disturbing force has a very high frequency. In such a case, the ratio ω^2/ω_n^2 is a large number and the magnification factor approaches zero. When ω approaches ω_n, *i.e.*, the frequency of the disturbing force approaches the frequency of natural vibrations of the system and the damping forces are small, the magnification factor becomes large. This means that a small periodical disturbing force may produce very large forced vibrations provided it is in **resonance** with the natural vibrations of the system.

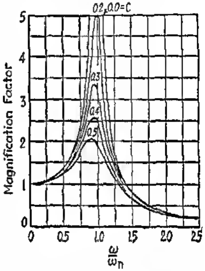

FIG. 2.—The Magnification Factor and the Coefficient of Damping.

From Eq. (12) it is seen that the forced vibration always lags behind the disturbing force. When c is small and ω is considerably less than ω_n, the difference of phase α is small. When ω approaches ω_n, a sharp variation in the phase of the forced vibrations takes place and at resonance α becomes equal to $\pi/2$. When ω is considerably larger than ω_n, the difference of phase approaches the value $\alpha = \pi$.

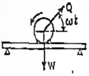

FIG. 3.

An example of forced vibrations is the vibrations produced by an unbalance of a rotating machine. Taking into consideration the vertical component of the centrifugal force Q only (Fig. 3), the disturbing force will be $Q \sin \omega t$. Heavy vibrations will be produced by this force when the number of revolutions of the machine per second approaches the frequency of the natural vibration of the system consisting of the mass of the machine and of the beams supporting the machine.

The Energy Method. The vibration problem of a system such as shown in Fig. 1 can be solved by a consideration of the energy of the system. This energy method is

in the bearings are such that free displacements of the cross sections $m - n$ and $m_1 - n_1$ during twist are possible, every crank can be replaced by an equivalent shaft of uniform cross section of an arbitrarily chosen torsional rigidity C. The length of the equivalent shaft will be found from the equation

$$l = C[(2b/C_1) + (a/C_2) + (2r/B)] \quad (28)$$

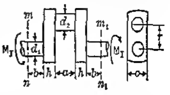

FIG. 11.

in which

$C_1 = \pi d_1^4 G/32$ = the torsional rigidity of the journal.

$C_2 = \pi d_2^4 G/32$ = the torsional rigidity of the crank pin.

$B = hc^3E/12$ = the flexural rigidity of the web.

b = half the length of the main journals and a, d_1, d_2, etc., are the dimensions shown in Fig. 11. If there are no clearences at the bearings, the length of the equivalent shaft will be found from the equation

$$l = C[(2b/C_1) + (a/C_2)(1 - r/s) + (2r/B)(1 - r/2s)] \quad (29)$$

in which

$$s = \left[\frac{r(a+h)^2}{4C_3} + \frac{ar^2}{2C_2} + \frac{a^3}{24B_1} + \frac{r^3}{3B} + \frac{1.2}{G}\left(\frac{a}{2F} + \frac{r}{F_1}\right)\right] \Big/ \left(\frac{ar}{2C_2} + \frac{r^2}{2B}\right)$$

$$C_3 = c^3h^3G/3.6(c^2 + h^2); \qquad B_1 = \pi d_2^4 E/64$$

In actual conditions, the length of the equivalent shaft will depend on the magnitude of clearances and will have an intermediate value between the two extreme values given by Eqs. (28) and (29).

In the case of a **shaft with three rotating masses** (*Fig. 12*), let I_1, I_2, I_3 = *the moments of inertia of the* rotating masses about the axis of the shaft and k_1, k_2 = spring constants for the two portions of the shaft. Then the frequency equation will be

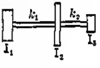

FIG. 12.

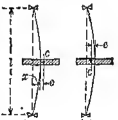
$$\frac{I_1I_2I_3}{k_1k_2}\omega_n^4 - \left(\frac{I_1I_2 + I_1I_3}{k_1} + \frac{I_2I_3 + I_1I_3}{k_2}\right)\omega_n^2 + (I_1 + I_2 + I_3) = 0 \quad (30)$$

from which the two frequencies of natural vibrations can be calculated. In the case of a shaft with many rotating masses as in the case of the Diesel engine, approximate numerical and graphical methods are usually applied in calculating frequencies of natural vibrations. (See Lewis, *Trans. Soc. Naval Architects Marine Eng.*, **33**, 1925, p. 109. See also Holzer, "Die Berechnung d. Drehschwingungen," Springer.) If a pulsating torque is acting on the shaft and the frequency of the torque approaches one of the frequencies of natural vibration of the shaft, the condition of resonance takes place and heavy forced torsional vibration will be produced.



(a) (b)

FIG. 13.

Critical Speed of a Rotating Shaft

It is known that rotating shafts at certain speeds, called critical speeds, become dynamically unstable and large vibrations are likely to develop. This phenomenon is due to resonance effects, and the critical speed for a shaft is that speed at which the number of revolutions per second of the shaft is equal to the frequency of its natural vibration.

The frequency of free vibration of such systems does not depend on the amplitude, *i.e.*, the vibrations are *isochronic*. There are cases where the spring constant of the vibrating system varies with the displacement and the restoring force is no longer proportional to the displacement. The natural frequency of systems involving such springs depends on the magnitude of the amplitude. By using such types of springs, the unfavorable effect of resonance can be diminished. If, due to the resonance, the amplitude of vibration begins to increase, the frequency of the vibration changes, *i.e.*, the resonance condition disappears. A simple example of such a spring is shown in Fig. 4. The flat spring, supporting the weight W, is built in at the end A. During vibration, the spring is partially in contact with one of two cylindrical surfaces AB or AC. Due to this fact, the free length of the cantilever varies with the amplitude so that the rigidity of the spring increases with increasing deflection, *i.e.*, the frequency of vibration increases with an increase in amplitude.

FIG. 4.

In Fig. 5, another example is given of a system in which the period of vibration depends on the amplitude. A body W performs vibrations between two springs by sliding without friction along the bar AB. This example illustrates the effect of clearance a on the frequency of vibration. The frequency will depend not only on the spring constant but also on the magnitude of the clearance a and on the initial conditions. Assume, for instance, that at the initial moment the body W is in its middle position and has an initial velocity v in the x-direction. Then the time necessary to cross the clearance a will be $t_1 = a/v$. After crossing the clearance, the body comes in contact with the spring and further motion in the x direction will be simple harmonic. The time during which the velocity is changing from v to 0 (quarter period of the simple harmonic motion) will be [see Eq. (4)] $t_2 = \pi\sqrt{W/kg}/2$. The period of a complete cycle of vibration is

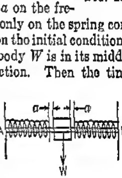


FIG. 5.

$$T = 4(t_1 + t_2) = (4a/v) + 2\pi\sqrt{W/kg} \tag{21}$$

It is seen that the period is very large for very small values of v and decreases with increase of v. If a periodic disturbing force, having a period larger than $2\pi\sqrt{W/kg}$ is acting, it will always be possible to give to the body W such an initial velocity that the corresponding period T will become equal to the period of the disturbing force and in such manner resonance conditions will be established. Some heavy vibrations in machines with clearances and in electric locomotives have been explained in this manner.

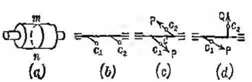

FIG. 6.

Balancing of Rotating Machines. One of the most important applications of the theory of vibrations is in the solution of balancing problems. It is known that a rotating body does not exert any variable disturbing action on the supports when the axis of rotation coincides with one of the principal axes of inertia of the body. It is difficult to satisfy this condition exactly in the process of manufacturing, because, due to errors in geometrical dimensions and non-homogeneity of the material, some irregularities in the mass

The value obtained by using in this formula the static loads W and the corresponding deflections y is generally within 1 percent of the correct value. By repeating the calculation, using W_1y_1, W_2y_2, W_3y_3, W_4y_4 . . . as the concentrated loads acting on the shaft and finding the corresponding deflections y_{1a}, y_{2a}, y_{3a}, y_{4a}, and then writing for the correct value N_c,

$$N_{c1} = N_c\sqrt{\frac{W_1y_1 + W_2y_2 + W_3y_3 + W_4y_4 + \cdots}{W_1y_{1a} + W_2y_{2a} + W_3y_{3a} + W_4y_{4a} + \cdots}} \tag{33}$$

a closer approximation to the true critical speed will be obtained, as the values y_{1a}, y_{2a} . . . will correspond more nearly to the elastic curve of the shaft *at the critical speed*. Similarly, by repeating the calculation again will W_1y_{1a}, W_2y_{2a} . . . as loads and finding corresponding deflections y_{1b}, y_{2b} . . . a still closer approximation to the true critical speed will be obtained. Unless, however, extreme care is taken to avoid cumulative errors of computation, the increased accuracy obtained for successive trials is likely to be to a large extent illusory, and of no practical value. If the shaft carries any distributed loads, they should be replaced by approximately equivalent concentrated loads before using Eq. (32). In case the loads W_1, W_2, W_3, W_4 . . . are not all on the same span (*e.g.*, on a three-bearing shaft), the loads on one span *must be assumed as acting vertically downward, and those on the other* vertically upward, so as to preclude the possibility of a zero deflection at any point except at the bearings. The same rule applies when the shaft has three or more spans.

In practice, the loads are usually shrunk on the shaft so that its stiffness (or its moment of inertia) at the loads is greatly increased; the loads are not exactly concentrated at the assumed points; and, finally, the gyroscopic action of the loads on the bent shaft, especially toward the bearings, tends to

Table 1. Critical Speeds of Shafts with a Single Concentrated Load

* One bearing, R_1; load W applied at free end of shaft, at distance l from bearing.

Balancing of Reciprocating Machines

For the calculation of the unbalanced forces in a single cylinder-crank mechanism, the moving parts are divided into a reciprocating weight and a rotating weight. The reciprocating weight W_{rec} consists of the piston and a fraction of the connecting rod. For this purpose, the connecting rod is laid horizontally on two scales, one under the crank-pin end and one under the piston-pin end. The fraction of the weight so found under the piston-pin end should be added to the weight of the piston to find the reciprocating weight. The rotating weight W_{rot} again consists of two parts. The first of these is *a weight so chosen that if it is concentrated at the crank-pin center* it causes a centrifugal force equal to that of the entire crank structure, including the counterbalance; the second is that fraction of the connecting rod found on the scale under the crank-pin end. The sum of these two contributions is the rotating weight W_{rot}. It is clear that W_{rec} is always positive, but that W_{rot} may be made zero or even negative by counterweighting the crankshaft.

The alternating unbalanced forces caused by these two weights are usually divided into *primary* forces, alternating once per revolution, and *secondary* forces, alternating twice per revolution. For a single crank, these forces are as follows:

$$\text{Primary}\begin{cases}\text{along cyl. center line, } (W_{rec} + W_{rot})\omega^2 r/g = F_1\\ \text{across cyl. center line, } W_{rot}\omega^2 r/g = F_2\end{cases}$$

$$\text{Secondary}\begin{cases}\text{along cyl. center line, } W_{rec}\omega^2 r^2/gl = F_3\\ \text{across cyl. center line, zero}\end{cases}$$

In these expressions, r is the crank radius, l the connecting rod length between its two bearing center, and ω the angular engine speed, in radians per second. By counterbalancing, one of the primary components can be reduced to zero, but the other primary as well as the secondary force cannot be eliminated. For a two-cylinder engine with 180 deg cranks, both primary forces are equal and opposite in direction for the two cylinders, so that a two-cylinder engine is in "primary force balance." However, the forces of the two cylinders are not in line, so that they form a couple; thence a two-cylinder engine is "unbalanced for primary moments."

No. of cylinders	Crank arrangement	Primary force		Secondary force longitudinal	Primary moment of		Secondary moments
		Longitudinal	Lateral		Long. force	Lat. force	
1	....	F_1	F_2	F_3			
2	0–180	0	0	$2F_3$	F_1l	F_2l	
3	0–120–240	0	0	0	$\sqrt{3}F_1l$	$\sqrt{3}F_2l$	$\sqrt{3}F_3l$
4	0–180–180–0	0	0	$4F_3$	0	0	
4	0–90–270–180	0	0	0	$\sqrt{10}F_1l$	$\sqrt{10}F_2l$	0
5	0–72–144–216–288	0	0	0	Unbalanced	Unbalanced	Unbalanced
6	0–120–240–240–120–0	0	0	0	0	0	0
7	Equal intervals of 360°/7	0	0	0	Unbalanced	Unbalanced	Unbalanced
8	0–180–90–270–270–90–180–0	0	0	0	0	0	0

In this table l is the distance between cylinder centerlines.

straighten out the shaft. For these reasons, the value of N_c as computed by Eq. (32) will usually be found to be somewhat low.

If a single load W_1 alone is acting on the (weightless) shaft, Eq. (32) becomes

$$N_c = 187.7/\sqrt{y} \tag{34}$$

and in this form it is occasionally applied to single-span shafts carrying more than one load by taking for y the *maximum* deflection of the shaft, no matter where it occurs.

A shaft may have as many critical speeds as the number of loads it carries. A shaft carrying a distributed load may therefore have an infinite number of critical speeds. For engineering purposes, only the first critical speed is usually of importance, while the second critical speed is only occasionally reached. For shafts of uniform or average diameter d (in.), carrying one or two concentrated loads or a uniformly distributed load (lb), formulas for the critical speed can be written down directly. Tables 1 and 2 are for steel shafts having a modulus of elasticity $E = 29{,}000{,}000$. Table 1 gives the single critical speed N_c. Table 2 gives directly or indirectly the two critical speeds N_{c1} and N_{c2}. In all cases, the weight of the shaft itself is either neglected, or a part of it (one-half to two-thirds) is added to the concentrated loads. Shafts with very short or self-aligning bearings are considered as *supported* at the bearings, and those with long rigid bearings as *fixed*.

As defined above, a shaft at its critical speed is in a state of maximum sensitiveness (or indifferent equilibrium), so that the smallest force may, if allowed sufficient time, deflect it to infinity and break it. The minutest deviation, however, from the mathematically exact critical speed is sufficient to restore to the shaft a considerable amount of its elastic resistance. In the neighborhood, therefore, of its critical speed a shaft merely undergoes more or less intense vibrations, which are generally transmitted also to the supporting frame. The deflecting force may be due to some external cause, but it is usually supplied by the almost unavoidable deviations of the centers of gravity of the various loads from the center line of the shaft. By reducing these deviations to a minimum by fine workmanship and very careful balancing, the vibration at the critical speed may be made scarcely noticeable.

Lateral Vibrations of Prismatical Bars

Let l = the length of the bar and $a = \sqrt{EIg/Ad}$, where EI = flexural rigidity of the bar, A = area of the cross section, d = weight per unit volume of the material of the bar; then the general equation for calculating frequencies of various types of natural vibration is

$$f_i = \alpha_i a/l^2 \tag{35}$$

The numerical values of the coefficient α_i depend on the conditions at the ends.

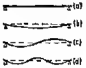

FIG. 14.

Bar with Simply Supported Ends. The consecutive types of natural vibrations shown in Fig. 14, have one, two, three . . . half-waves. The corresponding values of the factor α_i in Eq. (35) are

$$\alpha_1 = \pi/2; \quad \alpha_2 = 4\pi/2; \quad \alpha_3 = 9\pi/2; \quad \ldots \alpha_i = i^2\pi/2$$

The following tabulation gives values of α_i for three other cases of end support. Case I is for a bar with one end built in and the other free. Case II is for a bar with free ends or with built-in ends. Case III is for a bar with one end built in and the other end simply supported.

equal to one radian and I = moment of inertia of the stator about the same axis. Then the period of rotational vibration of the stator is [see Eq. (25) below]

$$T_n = 2\pi\sqrt{I/k} \tag{22}$$

Neglecting damping, the reduction of the torque transmitted to the foundation will be in the ratio [see Eq. (13)]

$$[(\omega^2/\omega_n^2) - 1]^{-1} = [(T_n^2/T^2) - 1]^{-1} \tag{23}$$

where T is the period of the pulsating torque acting on the stator.

In most cases, steel springs of various shapes may be used for mounting. Rubber springs are now available and are very convenient. The rubber usually is stressed in shear and is bonded to steel flanges which can be attached to the machine and to the floor with a common bolt connection. They are manufactured by the Goodrich Co., Akron, Ohio, under the trade name of "Vibro Insulators" and are available in several sizes. For the design of rubber supports in other cases, it is necessary to calculate the deflection characteristics of each design. Since these deflections are usually large in comparison with the original dimensions of the rubber, the ordinary formulas of strength of materials do not apply (see Smith, "Rubber Mountings," *Trans. A.S.M.E.*, A13, 1938).

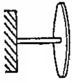

FIG. 9.

Torsional Vibrations of Shafts. The simplest case of torsional vibration is shown in Fig. 9 in which a circular disk is attached to the shaft. By twisting the shaft, torsional vibrations of the system can be produced.

Let

G = modulus of elasticity in shear.
I_p = polar moment of inertia of the circular cross section of the shaft.
$k = GI_p/l$ = the spring constant, *i.e.*, the torque necessary to produce an angle of twist equal to unity (one radian).
I = *moment of inertia of mass of the disk about the axis of the shaft.*
θ = the variable angle of twist of the shaft during vibration.

The differential equation of torsional vibration will be

$$I\ddot{\theta} + k\theta = 0 \tag{24}$$

and with the notation $\omega_n^2 = k/I$, the period of torsional vibration will be

$$T = 2\pi/\omega_n = 2\pi\sqrt{I/k} = 2\pi\sqrt{Il/GI_p} \tag{25}$$

In the case of a **system consisting of two disks** joined together by a shaft (Fig. 10), the disks will always rotate in opposite directions during vibration and there will be a nodal section mn which will remain stationary during oscillation. The distances l_1, l_2 of this section from the disks will be inversely proportional *to the moments of inertia of the disks.* Then $l_1 = lI_2/(I_1 + I_2)$ and $l_2 = lI_1/(I_1 + I_2)$. Substituting l_1 and I_1 instead of l and I in Eq. (25), the following equations for the system in Fig. 10 are obtained:

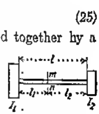

FIG. 10.

$$T = 2\pi\sqrt{I_1I_2l/(I_1 + I_2)GI_p}; \qquad f = \sqrt{(I_1 + I_2)GI_p/I_1I_2l}/2\pi \tag{26}$$

In the case of a shaft of variable cross section, such a shaft can always be replaced by an **equivalent shaft** of constant cross section noting only that a portion of a shaft of the length l and diameter d can be replaced, without changing the angle of twist of the shaft, by a portion of the length l_0 and diameter d_0 provided that

$$l_0 = ld_0^4/d^4 \tag{27}$$

In the case of **crankshafts** (Fig. 11) the problem of torsional rigidity depends on the conditions of constraint at the bearings. Assuming that the clearances

Bar of Variable Cross Section with Thicker End Built In and the Other End Supported. Assuming for I and A [Eqs. (37)] the approximate values of the fundamental and higher frequencies will be obtained by multiplying the corresponding frequencies of the prismatical bar with one end built in and another end supported (p. 518) with the factor (38) the constants β_i, β_i', γ_i, and γ_i' being taken from the table below:

i	β_i	γ_i	β_i'	γ_i'	i	β_i	γ_i	β'_i	γ_i'
1	0.431	0.569	0.626	0.857	4	0.494	0.506	0.628	0.662
2	0.480	0.520	0.612	0.724	5	0.496	0.504	0.631	0.654
3	0.490	0.510	0.623	0.680	6	0.497	0.503	0.633	0.649

Bar of Variable Cross Section with Free Ends. When the bar consists of two equal halves joined together at their thick ends, each half being generated by revolving the curve

$$y = ax^n \tag{39}$$

about the x-axis (x measured from the free ends) the frequency of the fundamental natural vibration will be given by Eq. (35). The constant α_i for various values of n in Eq. (39) is given below

$$\begin{array}{llllll} n &= 0 & \tfrac{1}{4} & \tfrac{1}{2} & \tfrac{3}{4} & 1 \\ \alpha_i &= 3.58 & 4.47 & 5.26 & 5.96 & 6.52 \end{array}$$

Vibration of Turbine Blades. Considering the blade as a cantilever bar of variable cross section built in at its thick end, the frequencies of natural vibrations in each of the two principal flexural planes of the blade will be obtained from the equation

$$f = \sqrt{f_1^2 + f_2^2} \tag{40}$$

in which f_1 denotes the frequency of the blade when the rotor is stationary, and f_2 represents the frequency of the blade when the elastic forces are neglected and only the restoring action due to centrifugal force is taken into consideration. Assuming that the variation of the cross-sectional area and of the moment of inertia along the blade are given by Eqs. (36), the frequency f_1 of the fundamental type of vibration can be calculated by using the table following Eq. (36), the frequency f_2 will be found from the equation

$$f_2 = \beta\omega/2\pi \tag{41}$$

in which ω = angular velocity of the turbine and β = the constant given in the table below for various values of the ratio a/l, where a = the radius of the rotor at the built-in end of the blade, l = the length of the blade, and c is defined by Eq. (36).

a/l	$c = 0$	$c = .2$	$c = .4$	$c = .6$	$c = .8$	$c = 1.0$
0	1.00	1.00	1.00	1.00	1.00	1.00
1	1.57	1.58	1.59	1.61	1.64	1.71
2	1.98	2.00	2.01	2.04	2.09	2.19
4	2.62	2.64	2.66	2.70	2.77	2.92
6	3.13	3.15	3.18	3.23	3.31	3.50
8	3.56	3.59	3.62	3.68	3.78	4.00
10	3.95	3.98	4.02	4.08	4.19	4.44

Vibrations of Membranes

Assumed that the membrane is a perfectly flexible and infinitely thin sheet of uniform material and thickness and that it is uniformly stretched in all

Shaft with One Disk. In order to exclude from our consideration the effect of the weight of the shaft and of the disk, a vertical shaft will be considered (Fig. 13). Let C be the center of gravity of the disk (Fig. 13a).

e = a small eccentricity.
ω = the angular velocity of the rotating shaft.
x = the deflection of the shaft at the disk.
W/g = the mass of the disk.

Then the centrifugal force acting on the shaft will be

$$W\omega^2(x + e)/g \tag{a}$$

The elastic reactive force with which the shaft is acting on the disk will be equal to

$$kx \tag{b}$$

where k is the spring constant of the shaft. In the case of a shaft of a uniform cross section and with the disk attached at the middle, $k = 48EI/l^3$.

Equating (a) and (b), we obtain $W\omega^2(x + e)/g = kx$ from which

$$x = e/[(\omega_n^2/\omega^2) - 1]$$

where $\omega_n^2 = kg/W$

It can be concluded that the deflection x tends to increase rapidly as ω approaches p, *i.e.*, when the number of revolutions per second of the shaft approaches the frequency of the lateral vibrations of the shaft and disk. The critical value of the speed will be

$$\omega_{cr} = \sqrt{gk/W} \tag{31}$$

At speeds higher than the critical, the center of gravity C will be situated as shown in Fig. 13b and the equation for determining x will be

$$W\omega^2(x - e)/g = kx$$

from which

$$x = e/[1 - (\omega_n^2/\omega^2)]$$

It is seen that for speeds above critical, with increasing ω the deflection x decreases and approaches the limit e, *i.e.*, at very high speeds the center of gravity of the disk approaches the line joining the supports and the deflected shaft rotates about the center of gravity C.

The critical speed of a rotating shaft is the speed at which its elastic forces are completely neutralized so that it is incapable of offering any resistance to a deflecting force. This speed is equal numerically to the frequency of vibration of the shaft with the masses mounted on it, if deflected by an external force while the shaft is at a standstill. Its value depends on the length of the shaft, its various diameters, the manner in which it is supported, and on the magnitude and distribution of the loads it carries, but it is independent of whether the shaft is horizontal or vertical.

Shafts of Uniform Diameter. If a shaft on two supports carrying loads $W_1, W_2, W_3, W_4 \ldots$ (lb) has such dimensions that the static deflections at those loads, if the shaft were horizontal (although actually it may be vertical), would be $y_1, y_2, y_3, y_4 \ldots$ (in.), respectively, the first or lowest critical speed N_c in rpm is given by the formula

$$N_c = 187.7\sqrt{\frac{W_1y_1 + W_2y_2 + W_3y_3 + W_4y_4 + \ldots}{W_1y_1^2 + W_2y_2^2 + W_3y_3^2 + W_4y_4^2 + \ldots}} \tag{32}$$

For the fundamental type of vibration of a square plate,

$$f = (\pi/a^2)\sqrt{gD/dh} \tag{46}$$

Consecutive frequencies of a **square plate** with free edges are given by the equation

$$f_i = (\alpha_i/2\pi a^2)\sqrt{gD/dh} \tag{47}$$

in which α_i is a constant depending on the mode of vibration. For the three lowest modes, the values of this constant are

$$\alpha_1 = 14.10; \quad \alpha_2 = 20.56; \quad \alpha_3 = 23.91$$

Circular Plate Clamped at the Boundary. Equation (47) can be used for calculating frequencies, a denoting in this case the radius of the boundary. Denoting with s the number of nodal circles and with n the number of nodal diameters, the magnitude of the factor α_i in Eq. (47) will be given by the following table. The table also gives values of α_i in Eq. (47) for a **circular plate with free boundary.**

s	Plate clamped at boundary			Plate with free boundary			
	$n = 0$	$n = 1$	$n = 2$	$n = 0$	$n = 1$	$n = 2$	$n = 3$
0	10.21	21.22	34.84	.....	.....	5.251	12.23
1	39.78	.....	.....	9.076	20.52	35.24	52.91
2	88.90	.....	.....	38.52	59.86		

Circular Plate Fixed at the Center. The constant α_i for consecutive modes of vibration having s nodal circles is as follows:

s = ...	0	1	2	3
α_i = ...	3.75	20.91	60.68	119.7

Vibration of Turbine Disks. It is well established that fractures which occur in turbine disks and which cannot be explained by defects in the material or by excessive stresses due to centrifugal forces may be attributed to flexural vibrations. Experiments show that such vibrations, at certain speeds of the turbine, become very pronounced and produce great additional bending stresses which may result in fatigue of the metal and in the gradual development of cracks, which usually start at the boundaries of the steam balance holes and other discontinuities in the web of the turbine disk where stress concentration is present. The most important cause producing these vibrations in turbine disks is that due to non-uniform steam pressure along the circumference. A localized pressure acting on the rim of a rotating disk is sufficient at certain speeds to maintain lateral vibrations in the disks. Experiments show that the failure should be attributed to those types of vibration having several diameters as nodal lines. These vibrations can be considered as combinations of two waves traveling circumferentially in the direction of rotation and in the opposite direction. The amplitudes of backward moving waves are usually larger than those of forward moving waves. Backward moving waves become especially pronounced under conditions of resonance when the backward speed of these waves in the disk coincides exactly with the forward angular velocity of the rotating disk so that the waves become stationary in space. This type of vibration is responsible in a majority of cases for disk failures. (See paper by

Table 2. Critical Speeds of Shafts Carrying Two Concentrated Loads
(The formulas are for shafts supported at the bearings)

General formula: N_{c1} and $N_{c2} = \sqrt{\frac{1}{2A}[U^2 + V^2 \mp \sqrt{(U^2+V^2)^2 - 4AU^2V^2}]}$

For N_{c1} use minus sign; for N_{c2} use plus sign. The values of A, U, and V are given in the table below, whenever N_{c1} and N_{c2} are not given directly. y_1 and y_2 = static deflections at W_1 and W_2 (shaft horizontal).

1		$A = 1 - \left(\frac{l^2 - a_1^2 - a_2^2}{2(l-a_1)(l-a_2)}\right)^2$ $U = 387{,}500\frac{d^2}{a_1(l-a_1)}\sqrt{\frac{l}{W_1}}$; $V = 387{,}500\frac{d^2}{a_2(l-a_2)}\sqrt{\frac{l}{W_2}}$
2		$N_{c2} = 548{,}000\frac{d^2}{a_1(l-2a_1)}\sqrt{\frac{l}{W_1}}$ $N_{c1} = 548{,}000\frac{d^2}{a_1}\sqrt{\frac{1}{W_1(3l-4a_1)}}$ $y_1 = \frac{W_1a_1^2}{6EI}(3l-4a_1)$
3		$A = 1 - \frac{(l+a)^2}{4l(l+c)}$ $U = 387{,}500d^2\sqrt{\frac{l}{W_1a^2b^2}}$; $V = 387{,}500\frac{d^2}{c\sqrt{W_2(l+c)}}$ $y_1 = \frac{W_1a^2b^2}{3EIl} - \frac{W_2ac}{6EIl}(l^2-a^2)$ $y_2 = \frac{W_2c^2}{3EI}(l+c) - \frac{W_1ac}{6EIl}(l^2-a^2)$
4		$A = 1 - \frac{9}{16}\ \frac{l}{l+c}$ $U = 1{,}550{,}000\frac{d^2}{l\sqrt{W_1l}}$; $V = 387{,}500\frac{d^2}{c\sqrt{W_2(l+c)}}$ $y_1 = \frac{W_1l^3}{48EI} - \frac{W_2cl^2}{16EI}$; $y_2 = \frac{W_2c^2(l+c)}{3EI} - \frac{W_1cl^2}{16EI}$
5		$C_1 = \frac{(l_1+a_1)^2}{4l_1(l_1+l_2)}$ $C_2 = \frac{(l_2+a_2)^2}{4l_2(l_1+l_2)}$ $A = 1 - \frac{C_1C_2}{(1-C_1)(1-C_2)}$ $U = 387{,}500\frac{d^2}{a_1b_1}\sqrt{\frac{l_1}{W_1(1-C_1)}}$; $V = 387{,}500\frac{d^2}{a_2b_2}\sqrt{\frac{l_2}{W_2(1-C_2)}}$
6		N_{c1} and $N_{c2} = 1{,}405{,}000\frac{d^2}{l\sqrt{W_1l}}\sqrt{1+m\mp\sqrt{1+m^2-1.388m}}$
7		$N_{c1} = 1{,}550{,}000\frac{d^2}{l\sqrt{W_1l}}$ $N_{c2} = 2{,}340{,}000\frac{d^2}{l\sqrt{W_1l}}$ $y_1 = \frac{7Wl^3}{768EI}$

lishes an air connection between the inside of the pipe and the ears. In use, the plunger is moved in the pipe very slowly till a pure singing note is heard. On the calibrated pipe, the corresponding frequency is read off. The instrument can be easily made up, the calibration being $f = 13{,}200/l$, where f = frequency, cycles per sec and l = length of pipe, inches.

Amplitude meters or vibrometers indicate amplitudes only and give no information regarding frequencies.

The vibrometer of the Vibration Specialty Co. (Philadelphia) is a seismic instrument with a natural frequency of 200 per min and very little damping, so that vibrations of frequencies above 500 per min can be measured. The relative motion of the weight and the frame is magnified 100 times. There is one indicator for horizontal and one for vertical vibrations on the same instrument which can be read simultaneously. Measurements can be made up to 2,200 cycles per min with the standard indicators and up to 4,000 cycles per min with special indicators, making the standard instrument fit for 1,800 rpm machinery. It is very rugged and intended for rough use in shops and power houses.

The vibrometer of Carl Schenk (Darmstadt, Germany) operates on the same principle as the previous ones. Its natural period is 40 per min, it has optical indicators, and can be used for frequencies from 200 to 5,000 per min. Both horizontal and vertical vibrations can be read on the same instrument. The magnification is 400 with the "precision" type or 75 with the "shop" type. The weights are critically damped, which is a great advantage.

The Davey Vibrometer (Vibroscope Inc., New York) is held still in space, and contact with the vibrating machine is established through a light pin. The relative motion sets a mirror vibrating which gives a band of light on a ground-glass scale. It can be bought with a magnification of 250 or 500. The low limit of frequency depends entirely on the kind of support. The upper frequency limit should be of the same order as the Schenk instrument on account of the optical magnification.

Vibrographs give a displacement-time record of the vibration.

The Geiger Vibrograph, Lehmann and Michels, Hamburg, Germany (See *Z. Ver. deut. Ing.* **60**, 1916, p. 811) can be used as a seismic instrument. Its magnification can be adjusted between 1:3 and 1:24. The record is traced on paper. A timing device tracing 1,500 cycle per min waves on the paper is built into the instrument. The seismic mass and spring can be easily replaced by others of different characteristics, so that it has a very wide frequency range. The standard instrument can be used from 500 up to 4,000 or 10,000 per min depending on the magnification. There is no damping in the instrument. Vibrations can be recorded in a vertical, horizontal, or any oblique direction. The seismic part can be removed and the instrument used as a direct vibration recorder with magnifications up to 72 times. In this case, the instrument itself should be held still in space by suspending it or holding it in the hands. The vibration is transmitted to the pen of the instrument by a light rod or needle. The instrument is capable of recording vibrations of small and light machinery, which is impossible with any seismic instrument. It can be changed to a torsiograph or stress recorder. Its disadvantage is the rather small magnification.

Tho Maihak Vibrograph (H. Maihak, Hamburg, Germany) is similar to Geiger's, but is a plain seismic instrument and cannot be transformed into a torsiograph or a direct recorder.

The Cambridge Vibrograph (Cambridge Instrument Co., Cambridge, England, see *Engineering*, 1925, p. 271) has a natural frequency of about 250 per min and no damping. To record vertical or horizontal vibrations two separate instruments are required, both on the seismic principle. The range of frequency is about 1,000 to possibly 10,000 per min. It records by means of a sharp needle on a band of celluloid, which is viewed through a hand microscope or can be microphotographed for reproduction. Its sensitivity is great; magnifications up to 2,000 give good pictures; amplitudes can be read to an accuracy of 0.01 mil. Since there is no provision for direct recording, the use of the instrument is restricted to heavy machines and structures.

Torsiographs. The Geiger **Torsiograph** (Lehmann and Michels, Hamburg) records non-uniformities of the angular rotation of shafts by means of the seismic principle. A very light aluminum pulley of 6 in. diameter carries inside itself a heavy steel flywheel, coupled to it by a flexible spiral spring. The pulley is driven, preferably by a steel

Case	α_1	α_2	α_3	α_4	α_5
I. Clamped-free	0.560	3.58	9.82	19.2	31.8
II. Free-free or clamped-clamped	3.58	9.82	19.2	31.8	47.5
III. Clamped-supported	2.45	7.96	16.6	28.4	43.3

Cantilever Bar of Variable Cross Section. If the variation of the cross-sectional area and of the principal moment of inertia of the cross section along the axis of the bar can be expressed in the form

$$A = a(1 - cx/l); \qquad I = b(1 - cx/l) \tag{36}$$

a, b, c being constants and x being measured from the built-in end, then the values of the coefficient α_i in Eq. (35) for the fundamental type of vibration are

$c =$	0	0.4	0.6	0.8	1.0
$\alpha_i =$	0.560	0.652	0.729	0.858	1.140

An approximate solution for a cantilever of variable cross section can be obtained by assuming that the variation of I and A along the axis of the bar (Fig. 15), measuring x from the built-in end, can be represented by the equations

$$I = I_0\left(1 - m\frac{x}{l} - m' \sin\frac{\pi x}{l}\right); \qquad A = A_0\left(1 - n\frac{x}{l} - n' \sin\frac{\pi x}{l}\right) \tag{37}$$

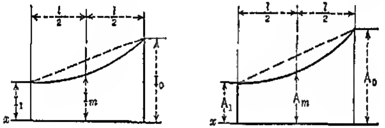

FIG. 15.

in which

$$m = (I_0 - I_1)/I_0; \qquad n = (A_0 - A_1)/A_0; \qquad m' = \frac{1}{I_0}\left(\frac{I_0 + I_1}{2} - I_m\right);$$

$$n' = \frac{1}{A_0}\left(\frac{A_0 + A_1}{2} - A_m\right)$$

Then the frequencies of the fundamental and higher modes of vibration will be obtained by multiplying the corresponding frequencies of the prismatical cantilever bar (see p. 518) with the factor

$$\sqrt{(1 - m\beta_i - m'\beta'_i)/(1 - n\gamma_i - n'\gamma'_i)} \tag{38}$$

The constants β_i, β_i', γ_i, and γ_i', for the consecutive modes of vibration are:

i	β_i	γ_i	β_i'	γ_i'	i	β_i	γ_i	β_i'	γ_i'
1	0.193	0.807	0.493	0.493	4	0.483	0.517	0.649	0.649
2	0.406	0.594	0.703	0.703	5	0.490	0.510	0.645	0.645
3	0.468	0.532	0.661	0.661	6	0.493	0.507	0.642	0.642

directions in its plane by a tension so large that the fluctuation in this tension due to the small deflections during vibrations can be neglected. Let

s = uniform tension per unit length of the boundary.
q = weight of the membrane per unit area.
A = the area of the membrane.

The frequency of the fundamental mode of vibration of the membrane is

$$f = (\alpha/2\pi)\sqrt{gs/Aq} \tag{42}$$

The constant α of this equation for various shapes of the boundary are as follows: circle, 4.261; square, 4.443; quadrant of a circle, 4.551; 60° sector of a circle, 4.616; rectangle, 3 × 2, 4.624; equilateral triangle, 4.774; semicircle, 4.803; rectangle, 2 × 1, 4.967; rectangle, 3 × 1, 5.736.

The frequencies of higher modes of vibrations of a rectangular membrane with the sides a and b, are given by the equation

$$f_{mn} = \frac{1}{2}\sqrt{\frac{gs}{q}\left(\frac{m^2}{a^2} + \frac{n^2}{b^2}\right)},\ \text{where } m = 1, 2, 3 \cdots;\ n = 1, 2, 3 \cdots \tag{43}$$

The frequencies of higher modes of vibrations of a circular membrane is given by the equation

$$f_{ns} = (\alpha_{ns}/2\pi a)\sqrt{gs/q} \tag{44}$$

in which

a = the radius of the boundary of the membrane.
α_{ns} = the constant given in the table below and depending on the number n of nodal diameters and the number s of nodal circles (the boundary circle is included in this number).

s	$n = 0$	$n = 1$	$n = 2$	$n = 3$	$n = 4$	$n = 5$	s	$n = 0$	$n = 1$	$n = 2$	$n = 3$	$n = 4$	$n = 5$
1	2.40	3.83	5.13	6.38	7.59	8.78	5	14.9	16.5	18.0	19.4	20.8	22.2

3	8.65	10.17	11.6	13.02	14.4	15.7	7	21.2	22.8	24.3	25.7	27.2	28.6
4	11.8	13.3	14.8	16.2	17.6	19.0	8	24.4	25.9	27.4	28.9	30.4	31.8

Vibration of Plates

It is assumed that the plate consists of a perfectly elastic, homogeneous, isotropic material and that it has a uniform thickness, considered small in comparison with its other dimensions. The deflections are assumed to be small in comparison with the thickness of the plates.

Let:

h = the thickness of the plate.
$D = Eh^3/12(1 - \nu^2)$ = the flexural rigidity of the plate.
d = weight per unit volume of the material of the plate.

The frequencies of the consecutive modes of vibration of a rectangular plate with the sides a and b and simply supported along the edges are

$$f_{mn} = \frac{\pi}{2}\sqrt{\frac{gD}{dh}}\left(\frac{m^2}{a^2} + \frac{n^2}{b^2}\right) \tag{45}$$

where $\quad m = 1, 2, 3 \cdots;\ n = 1, 2, 3 \cdots$

VIBRATION INSTRUMENTS

By J. P. DEN HARTOG

REFERENCES: Steuding, "Messung Mechanischer Schwingungen," V. D. I. Verlag. Timoshenko, "Vibration Problems in Engineering," Van Nostrand.

Many vibration instruments consist of a weight, suspended on springs in a frame, which is made to follow the vibration to be measured. They are based on the **seismic principle**.

Let the point of suspension A of a mass-spring system be given a motion $a \sin \omega t$. The mass will swing with the same frequency but with a different amplitude. The amplitude of the relative motion between the mass and the frame, as a function of ω, is shown in Fig. 1. For very slow motion of the frame (ω nearly zero), the spring will not extend at all; for a motion in resonance with the natural frequency of the system ω_n, the relative motion will be large, while for a very rapid motion of A (ω large), the mass cannot follow and will stand still in space so that the relative motion is a, or equal to the vibration of the frame. An instrument recording **vibration amplitudes**, therefore, should have a natural frequency which is low with respect to the frequency of the vibration to be measured.

The acceleration belonging to the motion $a \sin \omega t$ is $-a\omega t^2 \sin \omega t$; again a harmonic motion with the amplitude $a\omega^2$. The equation of the fully drawn curve in Fig. 1 is

$$\text{Relative motion} = a\omega^2/(\omega_n^2 - \omega^2)$$

which for small values of ω is nearly equal to $a\omega^2$. Therefore, **accelerometers** should have a natural frequency which is high with respect to the frequency of the acceleration to be measured.

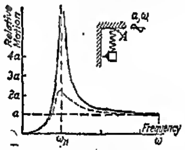

FIG. 1.—Vibration of Spring-suspended Weight.

A certain amount of **damping** is desirable in either class of instrument (dotted curve in Fig. 1). For the accelerometer, large damping is a fundamental necessity. An impure vibration contains, besides its fundamental frequency, many higher harmonic frequencies. An impure wave of 10 cycles per sec can cause resonance in systems with natural frequencies of 10, 20, 30, etc., cycles per sec, but not in a system of 5 cycles per sec. In an accelerometer, the natural frequency is higher than the measured frequency so that the danger of resonance always exists and can be avoided only by a great amount of damping. In a vibrograph, the natural frequency is lower than the measured one and no resonance can occur, so that such instruments can be built without much damping.

Frequency Meters. The **Fullarton Vibrometer** (Kelvin, Bottomley and Baird, Glasgow) is a single cantilever of which the length can be varied. The instrument is clamped to the structure under investigation, and at a certain length of the cantilever it responds. The corresponding frequency can be read off a scale.

The above instrument can be made for frequencies from 5 to about 100 cycles per sec. For frequencies higher than this, which may cause objectionable noise, the adjustable **organ pipe** is useful. It consists of a tube in which a plunger is inserted. The plunger has a small hole, which by means of rubber tubing and two stethoscope earpieces estab-

ejection from, the atom, thereby enabling it, because of its increased energy, to combine with other atoms to form molecules of either elementary substances or compounds. This convenient atomic model should be regarded as only a working hypothesis for coordinating a number of phenomena about which much yet remains to be known.

Chemical Elements[1]

Element	Symbol	Atomic weight*	Valence	Element	Symbol	Atomic weight*	Valence

* The atomic weights are based upon oxygen having a weight of 16.000 by definition.
[1] All the elements are metals, except as otherwise indicated.
[2] Inert gas. [3] Metalloid. [4] Liquid. [5] Gas.
[6] Most active gas. [7] Lightest gas. [8] Lightest metal. [9] Not placed.

Calculation of the Percentage Composition of Substances. Add together the atomic weights of the elements in the compound to obtain its molecular weight. Multiply the atomic weight of the element to be calculated by the number of atoms present (indicated in the formula by a subscript number) and by 100, and divide by the molecular weight of the compound. *For example, hematite iron ore (Fe_2O_3) contains 69.94 per cent of iron by weight, determined as follows:* Molecular weight of Fe_2O_3 = (55.84×2)

belt, from the shaft under test, and thus follows the motion of this shaft exactly. The flywheel, loose on its shaft, is dragged along by the spring and rotates uniformly on account of its great inertia. The relative motion of the two is recorded on the paper band in the same manner as with the vibrograph. The instrument is of great usefulness for the investigation of torsional vibrations of gas and Diesel engine applications.

Accelerometers. The Cambridge accelerometer is a seismic instrument with a high natural frequency and critical electromagnetic damping and has the same celluloid recording device as the Cambridge vibrograph. A single instrument can record vertical and horizontal accelerations simultaneously. By inserting different springs, it can be adapted to various uses approximately as follows:

Spring	a	b	c	d
Natural frequency per sec....................	24	29	43	71
Record can be read as close as	$g/400$	$g/200$	$g/100$	$g/30$
Max acceleration measured..................	$g/2$	g	$2g$	$6g$

Velocity Meters. A reversed ratio loudspeaker may be used for transforming the motions of a vibration into an alternating current which may then be passed through an amplifier and to an oscillograph, where it is either observed visually or recorded photographically. In such an electromagnetic device, the electric current or voltage is proportional to the velocity of motion. The loudspeaker element must be mounted on a seismic mass but the pick-up instrument can be made quite small. The instrument is made by the Sperry Gyroscope Co. (See Draper and Bentley, "Measurement of Aircraft Vibration During Flight," *Jour. Aeronautical Sciences*, 3, 1936, p. 116; and Hull, "Modern Aids to Vibration Study," *Trans. A.S.M.E.*, 1937, A-151.)

Stress recorders measure variations in strain. They are clamped or screwed to two points on the member to be tested and the relative motion of these points is recorded.

The Cambridge Stress Recorder has a gage length of 10 in. and scribes its record on a film of celluloid 15 times magnified. By optical magnification of this record, the stress for steel can be read with an accuracy of about 200 lb per sq in. It can be used for frequencies up to 90 per sec.

The Peters telemeter (Southwark Foundry and Machine Co., Philadelphia) is made in gage lengths of 2 and 8 in. It operates on the change in electrical resistance due to compression of a stack of thin carbon disks. Two carbon piles are built in each instrument, connected in a Wheatstone bridge circuit and recorded in an oscillograph. With the 8 in. gage length and a sensitive oscillograph, stresses in steel can be read with an accuracy of 200 lb per sq in. It is possible to have several telemeters in different places record simultaneously on the same oscillograph film. The instrument can be used for frequencies up to about 300 per sec. It can also be placed on the rotating part of machines; in that case, three slip rings have to be mounted on the shaft. The pile principle has been used also for a recording pressure gage and for an accelerometer for a special purpose.

The Moullin stress recorder (Cambridge Instrument Co.) operates with alternating current, utilizing the variation in reluctance due to the displacement of an iron core. The oscillograph record is not a definite line as with the previous instrument, but rather a band of light of which the envelope is to be read. It was originally built for use on airships. The same recording principle is also used on a torsion meter for measuring torque variations in a shaft.

The smallest strain recorder consists of a piece of carbon glued to the test member with a thin piece of paper in between for electrical insulation (see p. 440). By inserting the carbon in one of the branches of a Wheatstone bridge, and by amplifying, these variations can be recorded on an oscillograph (Kearns and Guerke, "Vibration Stress Measurements in Strong Centrifugal Field," *Trans. A.S.M.E.*, 1937, A-156).

Approximate Specific Gravities and Densities

(Water at 39 F and normal atmospheric pressure taken as unity)

Compressibility of Liquids

If v_1 and v_2 are the volumes of the liquids at pressures of p_1 and p_2 atm, respectively at any temperature, the coefficient of compressibility b is given by the equation

$$b = \frac{1}{v_1} \times \frac{v_1 - v_2}{p_2 - p_1}.$$

The value of $b \times 10^6$ for oils at low pressures at about 70 F varies from about 55 to 80; for mercury at 32 F it is 3.9; for chloroform at 32 F it is 100 and increases with the temperature to 200 at 140 F; for ethyl alcohol it increases from about 100 at 32 F and low pressures to 125 at 104 F; for glycerin it is about 24 at room temperature and low pressure.

Volume of Water as a Function of Pressure and Temperature
(From "International Critical Tables")

Temperature, deg F (C)	Pressure in atmospheres								
	0	500	1,000	2,000	3,000	4,000	5,000	6,500	8,000

Composition of Air

The percent volumetric composition of dry air at sea level is N_2, 78.03; O_2, 20.99; A, 0.94; CO_2, 0.03; H_2, 0.01; Ne, 0.00123; He, 0.0004; Kr, 0.00005; Xe, 0.000006. For ordinary purposes, this is taken as N_2, 79; O_2, 21. On this basis, the ratio of N_2 to O_2 is 3.76. On the basis of mass or weight, the percent composition is N_2, 75.5; O_2, 23.2; A, 1.33; CO_2, 0.045 or approximately N_2, 76.8; O_2, 23.2 and the nitrogen-oxygen weight ratio is 3.32 (data from "International Critical Tables," vol. 1, p. 393, McGraw-Hill).

GENERAL PROPERTIES OF MATERIALS

BY

H. W. BEARCE

(Originally prepared by Louis A. Fischer)

Chemistry

Every elementary substance is made up of exceedingly small particles called **atoms** which are all alike and which cannot be further subdivided or broken up by **chemical processes**. It will be noted that this statement is virtually a definition of the term elementary substance and a limitation of the term chemical process. There are as many different classes or families of atoms as there are **chemical elements**.

Two or more atoms, either of the same kind or of different kinds, are, in the case of most elements, capable of uniting with one another to form a higher order of distinct particles called **molecules**. If the molecules or atoms of which any given material is composed are all exactly alike, the material is a **pure substance**. If they are not all alike, the material is a **mixture**.

If the atoms which compose the molecules of any pure substance are all of the same kind, the substance is, as already stated, an **elementary substance**. If the atoms which compose the molecules of a pure chemical substance are not all of the same kind, the substance is a **compound substance**.

The atoms are to be considered as the smallest particles which occur separately in the structure of molecules of either compound or elementary substances, so far as can be determined by ordinary chemical analysis. The molecule of an element consists of a definite (usually small) number of its atoms. The molecule of a compound consists of one or more atoms of each of its several elements, the numbers of the various kinds of atoms and their arrangement being definite and fixed, and determining the character of the compound. This notion of molecules and their constituent atoms is useful for interpreting the observed fact that chemical reactions—*e.g.* the analysis of a compound into its elements, the synthesis of a compound from the elements, or the changing of one or more compounds into one or more different compounds—take place so that the masses of the various substances concerned in a given reaction stand in definite and fixed ratios.

It appears from recent researches that some substances which cannot by any available means be decomposed into simpler substances and which must therefore be defined as elements, are continually undergoing spontaneous changes or **radioactive transformation** into other substances which can be recognized as physically and chemically different from the original substance. Radium is an element by the definition given and may be considered as made up of atoms. But it is assumed that these atoms, so called because they resist all efforts to break them up and are therefore apparently indivisible, nevertheless split up spontaneously, at a rate which scientists have not been able to influence in any way, into other atoms, thus forming other elementary substances of totally different properties.

The view generally accepted at present is that the atoms of all the chemical elements, including those not yet known to be radioactive, consist of several kinds of still smaller particles, two of which are known as protons and electrons. The protons with other particles are bound together in the atomic nucleus and are positively charged. The electrons are negatively charged particles, all alike, external to the nucleus, and sufficient in number to neutralize the nuclear charge in an atom. The differences between the atoms of different chemical elements are due to the different numbers of these smaller particles composing them. According to the original Bohr theory, an ordinary atom is conceived as a stable system of such electrons revolving in closed orbits about the nucleus like the planets of the solar system around the sun. In a hydrogen atom, there is one proton and one electron; in a radium atom, there are 88 electrons surrounding a nucleus 226 times as massive as the hydrogen nucleus. Only a few, in general the outermost or valence electrons of such an atom, are subject to rearrangement within, or

Semisteel is a term that is now obsolete and is no guarantee of any specific or useful property in the metal.

Puddled iron (steel) is wrought iron (steel) made by the puddling process. Puddled steel is necessarily slag bearing.

Pig Iron

Iron ore is reduced in a blast furnace to form **pig iron**, which is the raw material for practically all iron and steel products. Nearly 90 percent of the iron ore mined in the United States comes from the Lake Superior region; this ore has the advantages of high quality and the cheapness with which it can be mined and transported by way of the Great Lakes. The ore consists mainly of hematite (Fe_2O_3) and contains 50 to 70 percent iron. Other important iron-ore districts in the United States are in Alabama, in the Adirondacks in New York, and in Pennsylvania.

The **blast furnace** consists of a vertical shaft over 20 ft diam and 100 ft high containing a descending column of iron ore, coke, and limestone and a large volume of ascending hot gas. The gas is produced by the burning of the coke in the hearth of the furnace and contains about 34 percent carbon monoxide. This gas reduces the iron ore to metallic iron which melts and picks up considerable quantities of carbon, manganese, phosphorus, sulphur, and silicon. The gangue (mostly silica) of the iron ore and the ash in the coke combine with the limestone to form the blast-furnace slag. The pig iron and slag are drawn off at intervals from the hearth through the iron notch and cinder notch, respectively. The modern blast furnace produces 100 to 1,200 tons of pig iron per day. To produce 1 ton of pig iron requires approximately 2 tons of iron ore, 1 ton of coke, half a ton of limestone, and 4 tons of air.

Wrought Iron

Manufacture. Pig iron is heated in a puddling furnace at a temperature somewhat above its melting point with the addition of iron oxides (ore, mill scale, etc.). The puddling furnace is a reverberatory furnace with an oxidizing flame which plays over the bath of molten metal. Air is allowed to enter the furnace and further promotes the oxidation. As the impurities are gradually burnt out of the iron, its melting point is raised so that the resulting purer metal forms in globules which are collected together by means of long iron rods manipulated by the puddler. This iron is not molten, but is taken from the furnace in a pasty condition in the form of balls and contains semi-molten slag (principally iron silicates) mechanically included. The ball is put through a squeezer or hammered with a steam hammer to remove a large portion of the slag and is now called a **bloom**. It passes through a rolling mill and is then known as **muckbar**. The bars are usually sheared, piled crosswise, and the pile is reheated and rerolled with further removal of slag, the purer iron product being called **refined bar iron**. This is the wrought iron of commerce. When refined bar iron is sheared, piled, and rerolled in a similar manner, the resulting material is called **double-refined iron**.

In a new method of manufacturing wrought iron, known as the **Aston process** or **New Byers process**, a very-low-carbon ferrous metal is prepared in a suitable furnace, usually a Bessemer converter. The relatively pure molten iron is poured into a ladle containing slag of the proper composition. An instantaneous and violent action occurs upon solidification of the metal, with profuse gas liberation, and the metal becomes a pasty mass of iron

+ (16 × 3) = 159.68. Percentage of iron in compound = (55.84 × 2) × 100/159.68 = 69.94.

Solubility of Inorganic Substances in Water

Number of grams of the anhydrous substance soluble in 1,000 grams of water. The common name of the substance is given in parenthesis.

Uses. Wrought iron can be obtained in the form of plates, sheets, forging billets, structural shapes, bars, pipes, and tubing. The principal use for wrought iron is in the form of pipe used for mildly corrosive conditions. It is also used extensively for general forging purposes. Wrought iron was formerly used for making crucible steel, and is still employed by some manufacturers for that purpose.

Ingot Iron

Ingot iron (Armco iron) is a commercially pure iron which is made in a basic open-hearth furnace in a manner similar to steel. The refining operation is carried on considerably further by the addition of a very pure grade of iron ore which oxidizes out the impurities to a low point. A high furnace temperature is required for this operation owing to the high melting point of pure iron. A typical analysis of ingot iron is given in Table 1.

Physical Constants. Sp gr, 7.866; melting point, 2795 F; specific heat at 77 F, 0.108; heat of fusion, 36 Btu per lb; thermal conductivity at 212 F., 465 Btu per hr per sq ft per in. per deg F; thermal coefficient of expansion at 212 F, 7 millionths per deg F; electrical resistivity at 32 F, 9.50 michohm-cm; temperature coefficient of electrical resistance between 32 and 212 F, 0.0031 per deg F. Many of these constants are affected considerably by small changes in composition, grain size, or mechanical treatment.

Coal, coke	0.37–0.51	23–32

scrap, then melt the scrap with an oxidizing flame. When melting is well advanced, molten pig iron is added and a reaction takes place between the iron oxide and the impurities in the pig iron. The acid slag formed by the oxidation of silicon and manganese is run off, and with further heating the lime comes up through the bath causing a violent boil and forms a basic slag. This slag makes it possible to remove a large percentage of the phosphorus in the iron. When all the impurities are lowered to the desired extent, the metal is tapped through a hole in the rear of the furnace and poured into a ladle. Various additions are made to the steel either in the furnace before tapping, or in the ladle, to deoxidize the steel and to obtain the desired composition. The time required for the complete operation is 8 to 12 hr.

Acid-open-hearth steel is produced in an open-hearth furnace having an acid or siliceous lining. The process is very similar to the basic except that an acid slag is used so that no phosphorus can be removed from the steel. This requires a scrap and pig-iron charge of low phosphorus content.

Bessemer steel is made in a pear-shaped converter which is mounted on trunnions so as to be tilted easily for charging and pouring. Molten pig iron is poured into the converter, and air is blown through the liquid metal. Heat is liberated by the oxidation of the impurities—silicon, manganese, and carbon. When the carbon has been nearly eliminated, the metal is recarburized by the addition of alloys containing carbon, manganese, and silicon. From 8 to 20 tons of steel are made in one blow requiring only 10 or 15 min.

Acid Bessemer steel is made in a converter having a siliceous lining and is the only Bessemer steel made in the U. S., for our ores are not suitable for the production of pig iron for basic Bessemer steel. The latter is made in a converter having a magnesite lining, and limestone is added during the process to form a basic slag which removes a large proportion of the phosphorus in the pig. The process requires a pig iron very high in phosphorus, whereas the basic open-hearth process can use pig iron containing phosphorus in all but the highest amounts.

Electric Steel. Refining can be carried further in an electric furnace than in either the Bessemer converter or the open-hearth in consequence of better control of the composition of the slag and higher obtainable temperatures. The electric furnace commonly used in the production of electric steel is the **three-phase arc furnace** in which the electric arc heats the bath. The furnace has a basic lining and is usually charged with cold steel scrap. When the bath is molten, iron oxide is added to produce an oxidizing slag. The slag is then made reducing by the addition of carbon, some sulphur is removed, and the oxygen in the steel is greatly reduced. The desired composition is then obtained by the addition of the necessary alloys. The **induction furnace** is simply a melting furnace to which the various metals are added to make the desired alloy. When steel scrap is used as a charge, it will be a high-grade scrap the composition of which is well known.

Crucible steel is made in small graphite crucibles which are usually heated in regenerative gas furnaces. The process consists of melting iron together with various alloys, the purity of the product depending on the purity of the raw materials. This method of producing steel results in a high quality product but is almost obsolete.

Steel Ingots. After refining the steel by one of the preceding methods, the steel is tapped into a ladle and poured into iron ingot molds. Many

IRON AND STEEL

Classification of Iron and Steel

Iron (Fe) is not a high-purity metal commercially but contains other chemical elements which have a large effect on its physical and mechanical properties. The amount and distribution of these elements are dependent upon the method of manufacture. The most important commercial forms of iron are listed below. (Definitions are those given in the National Metals Handbook, 1939 ed.)

Pig iron is the product of the blast furnace and is made by the reduction of iron ore.

Cast iron is an alloy of iron containing so much carbon that, as cast, it is not appreciably malleable at any temperature.

White cast iron contains carbon in the combined form. The presence of cementite or iron carbide (Fe_3C) makes this metal hard and brittle, and the absence of graphite gives the fracture a white color.

Malleable cast iron is an alloy in which all the combined carbon in a special white cast iron has been changed to free or temper carbon by suitable heat-treatment.

Gray cast iron is a cast iron which, as cast, has combined or cementitic carbon not in excess of a eutectoid percentage—the balance of the carbon occurring as graphite flakes. The term "gray iron" is derived from the characteristic gray fracture of this metal.

Mottled cast iron is cast iron, the fracture of which is mottled, with white parts in which no graphite is seen and gray parts in which graphite is seen.

Ingot iron is an open-hearth iron very low in carbon, manganese, and other impurities.

Wrought iron is a ferrous material aggregated from a solidifying mass of pasty particles of highly refined metallic iron with which is incorporated, without subsequent fusion, a minutely and uniformly distributed quantity of slag.

Steel is a malleable alloy of iron and carbon, usually containing substantial quantities of manganese.

Carbon steel is steel that owes its distinctive properties chiefly to the carbon that it contains.

Alloy steel is steel that owes its distinctive properties chiefly to some element or elements other than carbon, or jointly to such other elements and carbon. Some of the alloy steels necessarily contain an important percentage of carbon, even as much as 1.25 percent. There is no agreement as to where the line between the alloy steels and the carbon steels shall be drawn.

Bessemer steel, open-hearth steel, crucible steel, and electric-furnace steel are steels made by the Bessemer, open-hearth, crucible, and electric-furnace processes, irrespective of carbon content.

Pipe, segregation, and inclusions are defects in the steel which cannot be remedied to any large extent. Surface defects such as seams, laps, and scabs can be removed by *chipping* the surface with air hammers, *scarfing* or *deseaming* with oxyacetylene torches, grinding, or, mechanically, by machining. To inspect the surface of steel products, the scale can be removed by *pickling* in acid, by the use of a torch in *flame scaling*, or by mechanical means.

Mechanical Treatment of Steel

At present, all but 2 or 3 percent of the total steel produced is cast in the form of ingots and then subjected to some form of mechanical treatment. The solid ingot is heated to between 2000 and 2600 F, depending on the composition of the steel, and then hot-worked by rolling, pressing, or hammering. **Hot work** consists of any mechanical treatment at temperatures above the thermal critical range of the steel. Considerable improvement in mechanical properties is obtained by hot work. It will increase to some extent the yield and tensile strength, but it is especially beneficial to the ductility of the steel since it breaks up the dendritic structure in the ingot and minimizes the effects of segregation and inclusions. The temperature at which hot work is completed is important and should be above, but as near as practicable to, the thermal critical range, the exact temperature depending upon the carbon and alloy content.

The effect of **rolling** is to elongate the inclusions in the direction of rolling, giving the steel excellent properties on samples taken parallel to this direction, although tests on samples taken in a transverse direction will not have as high mechanical properties. **Hammer forging** is more effective than rolling in that working can be done in more than one direction thus eliminating directional properties to the steel. The slow application of pressure in a **forging press** works the interior of a large forging more effectively than hammering; the press is used to a large extent for large high-quality forgings. Rolling, hammering, or pressing effectively breaks up the coarse crystallization of a cast ingot when a reduction in area of 3 or 4 to 1 has been obtained.

Shaping of steel by rolling is adopted whenever possible because of the rapidity of the operation and its relatively low cost. Rolling operations are carried out in mills which derive their name from the name of the product that they produce. Thus an ingot may be rolled into blooms in a blooming mill and slabs in a slabbing mill. In the blooming mill, the ingot is reduced by several passes to a **bloom**, having dimensions about 6 in. square or larger. The bloom may then be further reduced to a **billet** which is somewhere between 1½ and 6 in. square. The names blooms and billets still apply if the products are rectangular in form when the widths are less than twice the thickness. However, if the width far exceeds the thickness of the rectangular section, it is called a **slab**. Blooms are rolled on finishing mills into *structural shapes*, *rails*, *wheels*, *sheet bar* for further rolling into sheet, and **skelp** to be used in the manufacture of pipe. Blooms may also be used for forging purposes. Slabs are rolled into plates, and billets are rolled into rods, bars, bands, hoops, small shapes, and seamless tubes.

Cold work is work done on the metal below the thermal critical range and usually is done at atmospheric temperature. It greatly increases the yield strength and tensile strength, especially the former, and reduces the ductility. It includes all operations such as cold rolling, cold pressing, twisting, and wire drawing. Large tonnages of sheets are cold-rolled, which greatly

particles thoroughly mixed with slag. This pasty ball of iron is similar to the old puddled ball except that it is 6 or 7 times as large. The ball is taken to a squeezer and compacted into a 1,000 lb bloom which can be rolled directly into muckbar, slabs, rods, skelp, or any other desired form. In this process, no rabbling or agitation by hand or machine is required. The wrought iron produced has the metallographic characteristics and physical properties that are normal to a hand-puddled material, with an advantage of greater control of operation and of uniformity of product.

Composition. Typical analyses for hand-puddled and Byers wrought iron are given in Table 1. Wrought iron is distinguished from other irons in that it has a high phosphorus content and contains a large amount of slag inclusions.

Table 1. Typical Compositions of Wrought Iron, Ingot Iron, Electrolytic Iron, and Steel (Percent)

Material	C	Mn	P	S	Si	Slag by weight
Wrought iron (Hand puddled)	0.06	0.05	0.068	0.009	0.10	2.0
Wrought iron (Byers)	0.08	0.02	0.062	0.010	0.16	1.20
Ingot iron (Armco)	0.015	0.020	0.005	0.025	Trace	
Electrolytic iron	0.006		0.005	0.005	0.005	
Low-carbon steel	0.06	0.40	0.012	0.030	0.009	

Properties. Wrought iron can be readily worked and welded at temperatures close to its melting point. It is ductile when cold, has good forming qualities, and is said to be superior to mild steel in resistance to corrosion and fatigue failure. It has many practical applications owing to its ability to take on and hold protective metallic and paint coatings and its good machining and threading qualities. The mechanical properties of wrought iron are dependent upon the type of finished product. Table 2 gives the A.S.T.M. mechanical test requirements for single- and double-refined bars.

If austenite containing 0.80 percent carbon (eutectoid composition) is slowly cooled through the critical temperature, ferrite and cementite are rejected simultaneously, forming alternate plates or lamellae. This microstructure is called **pearlite** since when polished and etched it has a pearly luster. When examined under a microscope, however, the individual plates of cementite can easily be distinguished. If the austenite contains less than 0.80 percent carbon (hypoeutectoid composition), free ferrite will *first be rejected* on slow cooling through the critical until the composition of the remaining austenite reaches 0.80 percent carbon when the simultaneous rejection of both ferrite and carbide will again occur, producing pearlite. So a hypoeutectoid steel at room temperature will be composed of areas of free ferrite and areas of pearlite, the higher the carbon percentage, the greater the amount of pearlite present in the steel. When austenite containing more than 0.80 percent carbon (hypereutectoid composition) is slowly cooled, cementite is thrown out at the austenite grain boundaries, forming a cementite network until the austenite contains 0.80 percent carbon at which time pearlite is again formed. Thus, a hypereutectoid steel when slowly cooled will have areas of pearlite surrounded by a thin carbide network.

As the cooling rate is increased, the spacing between the pearlite lamellae becomes smaller; with the resulting greater dispersion of carbide preventing slip in the iron crystals, the steel becomes harder. Also with an increase in the rate of cooling, there is less time for the separation of excess ferrite or cementite and the equilibrium amount of these constituents will not be precipitated before the austenite transforms to pearlite. Thus with a fast rate of cooling, pearlite may contain more or less carbon than given by the eutectoid composition. When the cooling rate becomes very rapid (as obtained by quenching), the carbon does not have sufficient time to separate out in the form of carbide, and the austenite transforms to a highly stressed structure supersaturated with carbon called **martensite**. This structure is exceedingly hard but brittle and requires **tempering** to increase the ductility. Tempering consists of heating martensite to some temperature below the critical causing the carbide to precipitate in the form of small spheroids. The higher the tempering temperature, the larger the carbide particle size, the greater the ductility of the steel, and the lower the hardness.

In a carbon steel, it is possible to have a structure consisting either of parallel plates of carbide in a ferrite matrix, the distance between the plates depending upon the rate of cooling, or of carbide spheroids in a ferrite matrix, the size of the spheroids depending upon the temperature to which the hardened steel was heated. (Some spheroidization occurs when pearlite is heated, but only at high temperatures close to the critical temperature range.) At low tempering temperatures, the carbide particles are submicroscopic in size, therefore a hardened steel when tempered at a low temperature and examined under a microscope after etching will appear dark. This dark etching microstructure has been called **troostite**. When the carbide particles can be resolved under a microscope, the structure has been known as **sorbite**. Higher tempering temperatures cause the carbide spheroids to appear clearly, and the microstructure is usually referred to as a spheroidized structure. On account of the lack of a clear demarcation between troostite, sorbite, and a spheroidized structure, it is becoming customary simply to refer to the structure as **tempered martensite** and give the tempering temperature or the hardness of the product. The terms troostite and sorbite have for many years been used to denote very fine nodular pearlite and imperfectly developed pearlite formed in steels cooled just too slowly to be fully martensite, but this use of the terms is disappearing.

Heat-treating Operations

The following definitions of terms have been adopted by the A.S.T.M., S.A.E., and A.S.M. in substantially identical form.

Heat-treatment. An operation, or combination of operations, involving the heating and cooling of a metal or an alloy in the solid state, for the purpose of obtaining certain desirable conditions or properties.

Quenching. Rapid cooling by immersion in liquids or gases or by contact with metal.

Mechanical Properties. The average mechanical properties of ingot iron after various treatments are given in Table 3 (from A.S.M. Metals Handbook).

Young's modulus for ingot iron is 29,300,000 lb per sq in. in both tension and compression, and the shear modulus is 11,800,000 lb per sq in. Poisson's ratio is 0.28. The **effect of temperature** on the mechanical properties is shown in Table 4. The effect of **cold rolling** on the tensile strength, yield strength, elongation, and shape of the stress-strain curve is shown in Fig. 1. Armco iron welds evenly and easily; it holds paint well and has superior enameling properties; it has a high magnetic permeability at high inductions and low retentivity.

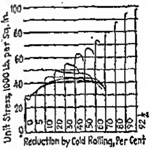

FIG. 1.—Effect of Cold Rolling on the Stress-strain Relations of Armco Ingot Iron. (Kenyon and Burns.)

Uses. In galvanized-sheet form for culverts, flumes, roofing, and siding; in plate form in oil tanks, water tanks, boilers, gas holders, and large pipe; in enameled form for ranges, refrigerators, tables and kitchen furniture, lighting fixtures, and similar articles. The purity of Armco iron makes it valuable as melting stock in making high-grade tool steel.

Electrolytic Iron

Electrolytic iron has been produced in commercial quantities since 1904 and has been useful in the production of metal with unusual properties. Many different processes have been tried out but, for economic reasons, most of them have been short-lived. The production of thin-wall large-diameter tubes has been successful since it is comparatively expensive to form them by rolling. Large revolving mandrels are used as cathodes, and a ferrous-chloride electrolyte is usually employed. It requires about 31 hr to plate 0.1 in. of iron in the form of a tube on the mandrel, but little labor or supervision is necessary, and a high percentage of satisfactory tubes is obtained. The tube is given a preliminary anneal to make it ductile and is then stripped off by special machines and reannealed to remove the hardness due to the cold-work of the stripping operation. Electrolytic iron is extremely brittle as deposited so that it can be readily pulverized to a fine powder, and this has been one way of producing a high-purity iron powder. Table 1 gives a typical analysis.

Mechanical Properties. Annealed electrolytic iron has tensile strength 35,000 to 40,000 lb per sq in.; yield strength, 10,000 to 20,000 lb per sq in.; elongation in 1.5 in., 40 to 60 percent; reduction of area, 70 to 90 percent. Large variations in mechanical properties will occur with change in amount of impurities, grain size, or previous mechanical or thermal treatment.

STEEL

Steel Manufacturing. Steel is produced from pig iron by the removal of impurities in either an open-hearth furnace, a Bessemer converter, or an electric furnace. In the United States, over 85 percent of steel is produced in the basic open-hearth furnace. This is a reverberatory furnace having a capacity up to 150 tons, although some special tilting furnaces have a capacity up to 400 tons. The hearth has a basic lining of magnesia and dolomite, and the roof is made of high-grade silica brick. A practice in wide use for making structural steels is to charge limestone, iron ore, and

"S curve." Various cooling rates are shown diagrammatically, and it will be seen that the faster the rate of cooling, the lower the temperature of transformation, and the harder the product formed. At around 1000 F, the austenite transforms rapidly to fine pearlite, and to form martensite it is necessary to cool very rapidly through this temperature range to prevent the formation of pearlite before the specimen reaches the temperature for the formation of martensite. The minimum rate of cooling that is required to form a fully martensitic structure is called the **critical cooling rate.** No matter at what rate the steel is cooled, the only products of transformation of this steel will be pearlite or martensite. However, if the steel is given an interrupted quench by quenching in a molten bath at some temperature between 400 and 1000 F, an acicular structure is obtained which is called **Bainite** and the heat-treatment is called **austempering.** Bainite has considerable toughness combining high strength with high ductility, and although austempering is not employed to any large extent today, it would appear to be a very promising method of heat-treating steels. Its limitation is that it can be applied only to articles of small cross section, for molten baths do not cool carbon steels sufficiently rapidly to prevent the formation of pearlite in samples more than ½ in. approx diam.

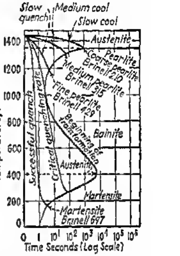

FIG. 3.—Influence of Cooling Rate on the Product of Transformation in a Eutectoid Carbon Steel.

The maximum hardness obtainable in a high-carbon steel with a fine pearlite structure is approximately 400 Brinell, although a martensitic structure would have a hardness of approximately 700 Brinell. Besides being able to obtain structures of greater hardness by forming martensite, a spheroidal structure will have considerably higher proof stress (*i.e.*, stress to cause a permanent deformation of 0.01 percent) and ductility than a lamellar structure of the same tensile strength and hardness. It is essential therefore to form martensite when optimum properties are desired in the steel. This can be done with a piece of steel having a small cross section by heating the steel above the critical and quenching in water; but when the cross section is large, the cooling rate at the center of the section will not be sufficiently rapid to prevent the formation of pearlite. The characteristic of steel that determines its capacity to harden throughout the section when quenched is called **hardenability.** This term should not be confused with the ability of a steel to attain a certain hardness. The intensity of hardening, *i.e.*, the maximum hardness of the martensite formed, is largely dependent upon the carbon content of the steel.

Three main factors affect the hardenability of steel: (1) austenite composition; (2) austenite grain size; and (3) amount, nature, and distribution of undissolved or insoluble particles in the austenite. The austenite composition will determine the position of the "nose" of the S curve, *i.e.*, the rate of decomposition, in the range of 1000 F. The slower the rate of decomposition, the larger the section that can be hardened throughout, and therefore the greater the hardenability of the steel. Everything else being equal, the higher the carbon content, the greater the hardenability. The question of austenitic grain size is of considerable importance in any steel that is to be heat-treated since it affects the properties of the steel to a considerable extent. When a steel is heated to just above the critical temperature, small polyhedral grains of austenite are formed. With increase in temperature, there is an increase in the size of grains, until at temperatures close to the melting point the grains are very large. The relation between the grain size developed and the heating temperature will vary considerably among steels

defects in rolled steel products may be introduced by incorrect ingot practice, and the production of high-grade steel requires great care at this stage.

High-quality machine and tool steels are deoxidized in the ladle with silicon and aluminum to such a degree that there is no gas evolution in the steel upon solidification, and they are called **killed** steels. When this steel cools in the mold, shrinkage of the steel on solidifying causes **piping**, the cavity or "pipe" being usually found in the upper portion of the ingot. To minimize this condition, a large-end-up mold is used together with a refractory "hot top" which supplies molten steel to the main body of the ingot while solidification proceeds. This minimizes the amount of metal that has to be discarded on account of pipe, but the top discard still amounts to 15 or 20 percent of the total weight of the ingot. In 1936, 15 percent of the total steel production was killed steel.

In order to reduce the cost of hot tops and large percentage of metal discard when making mild steel for structural purposes, the steel is not fully deoxidized. This results in blowholes in the steel on solidification; the presence of these blowholes minimizes piping by distributing throughout the ingot small voids instead of having one large one in the upper center of the ingot. If not exposed at the surface of the ingot, these blowholes weld together during rolling. Steel deoxidized in this manner is called **semikilled** steel. If the steel is deoxidized still less in the ladle, a reaction takes place during solidification in which the oxygen and the carbon in the steel form carbon monoxide which is freely evolved from the ingot. The intensity of this reaction affects the ingot structure greatly. If the reaction is allowed to go to completion, the product is called **rimmed** steel, but if the reaction is stopped after a short while by preventing, in a mechanical manner, further evolution of gas from the top of the ingot, the steel is called **capped** steel. The gas evolution results in an outer skin on the ingot which is clean and very low in carbon. In capped steel, the skin is thinner and there is less segregation or concentration of impurities than in rimmed steel. The presence of this nearly pure iron skin enables the production of an excellent surface finish on the rolled product, and therefore sheet and strip is made nearly exclusively from rimmed or capped steel.

Some defects besides the occurrence of pipe in rolled steel products are segregation, ingot cracks, seams, scabs, laps, and inclusions. **Segregation**, or the concentration of impurities, occurs in all steels upon solidification, but it can be minimized by proper mold design and low pouring temperatures. Rough mold surfaces or molds containing cracks or cavities interfere with the normal contraction of the ingot, and transverse cracks in the ingot skin may result. Cracks thus produced soon have their surfaces oxidized, and when the ingot is rolled out, these defects will be elongated in the direction of rolling and are called **seams**. Any oxidized crack or blowhole at the surface will roll out into a seam. Improper pouring conditions such as splashing of steel in the molds will form **scabs**. When rolling with grooved rolls which are not properly designed or set up, fins are liable to result from the flow of metal between the flat bodies of the rolls. If the fin is thin and wide, it will be folded over when the steel passes through the next set of rolls and will form a **lap**. **Non-metallic inclusions** consisting of sulphides, silicates, etc., are found to some extent in all steels and are introduced in the refining and deoxidation of the steel. Steels containing many inclusions are said to be "dirty," but the presence of these inclusions, unless they are large in size, is not necessarily detrimental to the physical properties.

than of plain carbon steel. The quenching operation does not have to be so drastic in the alloy steel as would be necessary to harden the plain carbon steel. Consequently, there is a smaller difference in temperature between the surface and center during quenching, and cracking and warping resulting from sharp temperature gradients in a steel during hardening can be avoided. The elements most effective in increasing the hardenability of steel are manganese, silicon, and chromium.

Such elements as molybdenum, tungsten, and vanadium are effective in increasing the hardenability when dissolved in the austenite, but they are usually present in the austenite in the form of carbides. The main advantage of these carbide-forming elements is that they prevent the agglomeration of carbides in tempered martensite. Tempering relieves the internal stresses in the hardened steel and causes spheroidization of the carbide particles with resultant loss in hardness and strength. The presence of these stable carbide-forming elements enables higher tempering temperatures to be used without sacrificing strength. This permits these alloy steels to have a greater ductility for a given strength, or, conversely, greater strength for a given ductility, than plain carbon steels.

The third factor which contributes to the strength of alloy steel is the presence of the alloying element in the ferrite. Any element in solid solution in a metal will increase the strength of the metal, so that these elements will materially contribute to the strength of hardened and tempered steels. The elements most effective in strengthening the ferrite are phosphorus, silicon, manganese, nickel, molybdenum, tungsten, and chromium.

A final important effect of alloying elements is their influence on the austenitic grain size. Martensite formed from a fine-grained austenite has considerably greater resistance to shock than when formed from a coarse-grained austenite. The oxides formed by the deoxidation of the steel by different elements apparently prevent grain growth above the critical temperature over a considerable temperature range. Aluminum is the most effective element to form grain-growth inhibitors, and most killed steels

Table 5. Trends of Influence of the Alloying Elements
(Bain, A.S.M. Metals Handbook, 1939)

Element	As dissolved in ferrite, strength	As dissolved in austenite, hardenability	As undissolved carbide in austenite, fine grain, toughness	As dispersed carbide in tempering, high temp strength, and toughness	As fine nonmetallic dispersion, fine grain, toughness
Al	Mild	Mild	None	None	Very strong
Cr	Mild	Moderate	Strong	Moderate	Slight
Co	*Strong*	*Negative*	None	None	None

improves their surface finish as well as increases their strength (see p. 573 for cold-rolled sheet).

Constitution and Structure of Steel

As a result of the methods of production, the following elements are always present in steel: carbon, manganese, phosphorus, sulphur, silicon, and traces of oxygen and aluminum. Various alloying elements are frequently added, such as nickel, chromium, copper, molybdenum, and vanadium. The most important of the above elements in steel is carbon, and it is necessary to understand the effect of carbon on the internal structure of the steel to understand the heat-treatment of carbon and low-alloy steels.

In Fig. 2 is the iron-iron carbide equilibrium diagram which shows the phases that are present in steels of various carbon contents over a range of temperatures under equilibrium conditions. Pure iron when heated to 1670 F changes its internal crystalline structure from a body-centered cubic arrangement of atoms, **alpha iron**, to a face-centered cubic structure, **gamma iron**. At 2535 F, it changes back to the body-centered cubic structure, **delta iron**, and at 2795 F the iron melts. When carbon is added to iron, it is found that it has only slight solid solubility in alpha iron (only 0.007 percent at room temperature). On the other hand, gamma iron will hold up to 1.7 percent carbon in solution at 2066 F. The alpha iron containing carbon or any other element in solid solution is called **ferrite**, and the gamma iron containing elements in solid solution is called **austenite**. Usually when not in solution in the iron, the carbon forms a compound Fe_3C (iron carbide) which is extremely hard and brittle and is known as **cementite**.

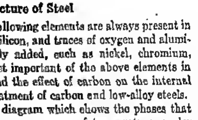

Fig. 2.—Iron-Iron Carbide Equilibrium Diagram.

The temperatures at which the phase changes occur are called **critical points** (or temperatures) and, in the diagram, represent equilibrium conditions. In practice there is a lag in the attainment of equilibrium, and the critical points are found at lower temperatures on cooling and at higher temperatures on heating than those given, the difference increasing with the rate of cooling or heating.

The various critical points have been designated by the letter *A*; when obtained on cooling, they are referred to as *Ar*, on heating as *Ac*. The various critical points are distinguished from each other by numbers after the letters, being numbered in the order in which they occur as the temperature increases. Ac_0 represents the magnetic change in cementite on heating; Ac_1, the beginning of transformation of ferrite to austenite on heating (line *PSK*); Ac_2, the magnetic change in ferrite on heating (line *MO*); Ac_3, the end of transformation of ferrite to austenite on heating (line *GOSK*); and Ac_4, the change from austenite to delta iron on heating (line *NJ*). On cooling, the critical points would be referred to as Ar_4, Ar_3, Ar_2, Ar_1, and Ar_0, respectively. It must be remembered that the diagram represents the pure iron-iron carbide system. The varying amounts of impurities in commercial steels affect to a considerable extent the position of the curves and especially the lateral position of point *S*.

Carbon steel in equilibrium at room temperature will have present both ferrite and cementite. The physical properties of the ferrite are approximately those of pure iron and are characteristic of the metal. The presence of cementite does not in itself cause steel to be hard, but rather it is the shape and distribution of the carbides in the iron that determines the hardness of the steel. The fact that the carbides can be dissolved in austenite is the basis of the heat-treatment of steel since the steel can be heated above the critical temperature (above line *GOSE* in the diagram) to dissolve all the carbides, and then suitable cooling through the cooling range will produce the desired size and distribution of carbides in the ferrite.

cooling rates (quenching) to form the hard martensitic structures. In selecting a **quenching medium** (see A.S.M. Metals Handbook), it is important to select the quenching medium for a particular job on the basis of size, shape, and allowable distortion before choosing the steel composition. It is convenient to classify steels in two groups on the basis of depth of hardening, *viz.*, shallow hardening and deep hardening. **Shallow-hardening steels** may be defined as those which, in the form of 1 in. diam rounds,

have, after brine quenching, a completely martensitic shell not deeper than $\frac{1}{4}$ in. The shallow-hardening steels are those of low or no alloy content, whereas the deep-hardening steels have a substantial content of those alloying elements that increase penetration of hardening, notably chromium, manganese, and nickel. The high cooling rates required to harden shallow-hardening steel produce severe distortion in all but simple, symmetrical shapes having a low ratio of length to diameter or thickness. Plain carbon steels cannot be used for complicated shapes where distortion must be avoided. In this case, water quenching must be abandoned and a less active quench used which materially reduces the temperature gradient during quenching.

Hardening. Heating and quenching certain iron-base alloys from a temperature either within or above the critical range for the purpose of producing a hardness superior to that obtained when the alloy is not quenched. Usually restricted to the formation of martensite.

Annealing is a heating and cooling operation implying usually a relatively slow cooling. The purpose of such a heat-treatment may be (1) to remove stresses; (2) to induce softness; (3) to alter ductility, toughness, electrical, magnetic, or other physical properties; (4) to refine the crystalline structure; (5) to remove gases; or (6) to produce a definite microstructure. The temperature of the operation and the rate of cooling depend upon the material being heat-treated and the purpose of the treatment. Certain specific heat-treatments coming under the comprehensive term annealing are as follows:

1. Full Annealing. Heating iron-base alloys above the critical temperature range, holding above that range for a proper period of time, followed by slow cooling to below that range. The annealing temperature is generally about 100 F above the upper limit of the critical temperature range, and the time of holding is usually not less than 1 hr for each inch of section of the heaviest objects being treated. The objects being treated are ordinarily allowed to cool slowly in the furnace. They may, however, be removed from the furnace and cooled in some medium that will prolong the time of cooling as compared with unrestricted cooling in the air.

2. Process Annealing. Heating iron-base alloys to a temperature below or close to the lower limit of the critical temperature range followed by cooling as desired. This heat-treatment is commonly applied in the sheet and wire industries, and the temperatures generally used are from 1020 to 1200 F.

3. Normalizing. Heating iron-base alloys to approximately 100 F above the critical temperature range followed by cooling to below that range in still air at ordinary temperature.

4. Patenting. Heating iron-base alloys above the critical temperature range followed by cooling below that range in air, in molten lead, or a molten mixture of nitrates or nitrites maintained at a temperature usually between 800 to 1050 F, depending on the carbon content of the steel and the properties required of the finished product. This treatment is applied in the wire industry to medium- or high-carbon steel as a treatment to precede further wire drawing.

5. Spheroidizing. Any process of heating and cooling steel that produces a rounded or globular form of carbide. The following spheroidizing methods are used. (1) Prolonged heating at a temperature just below the lower critical temperature, usually followed by relatively slow cooling. (2) In the case of small objects of high-carbon steels, the spheroidizing result is achieved more rapidly by prolonged heating to temperatures alternately within and slightly below the critical temperature range. (3) Tool steel is generally spheroidized by heating to a temperature of 1380 to 1480 F for carbon steels and higher for many alloy tool steels, holding at heat from 1 to 4 hr and cooling slowly in the furnace.

6. Tempering (also termed **drawing**). Reheating hardened steel to some temperature below the lower critical temperature, followed by any desired rate of cooling. Although the terms "tempering" and "drawing" are practically synonymous as used in commercial practice, the term "tempering" is preferred.

Figure 3 summarizes the rates of decomposition of a eutectoid carbon steel over a range of temperatures, the resulting curve being frequently called an

quenching medium, and finally the condition of the surface of the steel before quenching. Steel that carries a heavy coating of scale will not cool so rapidly as a steel that is comparatively scale free, and soft spots may be produced; or, in extreme cases, complete lack of hardening may result. It is therefore essential to minimize scaling as much as possible. Decarburization can also produce undesirable results such as non-uniform hardening and thus lower the resistance of the material to alternating stresses.

Tempering of fully hardened steel is carried out for relief of quenching stresses and for the recovery of a limited degree of toughness and ductility. The operation will give almost any desired combination of properties by proper selection of the time-temperature conditions. Table 8 gives the Brinell hardness obtained in several carbon and alloy steels when tempered for 1 hr at various temperatures. It should be emphasized that steel should

be tempered immediately after hardening to prevent cracking caused by internal stresses. When pyrometers are not available, the tempering temperatures may be controlled by the examination of the roughly polished surface of the metal. A thin film of oxide forms upon the steel, the color *of this film varying with the tempering temperature. Although it will vary* somewhat with different steels, the following temperatures are given with their corresponding colors: 400 F, faint straw; 440 F, straw; 475, deep straw; 520, bronze; 540, purple; 590, full blue.

The Relation of Design to Heat-treatment

Care must be taken in the design of a machine part to prevent cracking or distortion during heat treatment. With proper design the entire piece may be heated and cooled at approximately the same rate during the heat-treating operation. A light section should never be joined to a heavy section. Sharp reentrant angles should be avoided. Sharp corners and inadequate fillets produce serious stress concentration, causing the actual service stresses to build up to a point where they amount to 2 to 5 times the normal working stress calculated by the engineer in the original layout. The use of generous fillets is especially desirable with all high strength alloy steels.

It is well for the designer to remember that the modulus of elasticity of all commercial steels, either carbon or alloy, is the same so far as practical designing is concerned. The deflection under load of a given part is therefore entirely a function of the section of the part and is not affected by the composition or heat-treatment of the steel. Consequently if a part deflects excessively, a change in design is necessary; either a heavier section must be used or the points of support must be increased.

on account of variations in the deoxidation practice. By suitable deoxidation, steels can be made to be coarse grained at comparatively low temperatures, and others are fine grained over a considerable range of temperatures. Since the transformation of austenite usually starts at grain boundaries, a fine-grained steel will transform more rapidly than a coarse-grained steel because the latter has much less surface area bounding the grains than a steel with a fine grain size. Everything else being equal, coarse-grained austenite will have a higher hardenability than fine-grained. Small particles in the austenite will act as nuclei for the beginning of transformation in a manner similar to grain boundaries, and therefore the presence of a large number of small particles (sometimes submicroscopic in size) will result in low hardenability.

Determination of Austenitic Grain Size. The subject of austenite grain size is of considerable interest because of the fact that the grain size developed during heat-treatment has a large effect on the physical properties of the steel. In steels of similar chemical analysis, the steel developing the finer austenitic grain size will have a lower hardenability, but will, in general, have greater toughness, show less tendency to crack or warp on quenching, be less susceptible to grinding cracks, have lower internal stresses, and retain less austenite than coarse grained steel. It is for these reasons that most alloy steels are fine-grain steels. There are several methods of determining the grain-size characteristics of a steel, the one most commonly used in steel specifications being the **McQuaid-Ehn test.** In this test, a representative sample is carburized for 8 hr at 1700 F and cooled slowly. The high-carbon case on slow cooling will reject cementite at the austenite grain boundaries, and, by polishing and etching, the grains will be clearly seen under a microscope. There are several ways to report the grain size observed under the microscope, the one used most extensively being the A.S.T.M. index numbers. The numbers are based on the formula: number of grains per square inch at $100x = 2^{N-1}$, in which N is the grain-size index. The usual range in steels will be from 1 to 128 grains per sq in. at $100x$, and the corresponding A.S.T.M. numbers will be 1 to 8. Steels having an A.S.T.M. grain size of 1 to 4 are usually considered coarse-grained, and those from 5 to 8 are fine-grained steels. It should be noted that the McQuaid-Ehn test will give only the grain size developed in the steels when heated to one temperature for a given length of time. To determine fully the grain-size characteristics of a steel, tests should be made over a range of temperatures, but the McQuaid-Ehn test has proved of great help to both producers and consumers of steel since the test is inexpensive and reproducible. For further information on grain size, reference should be made to the A.S.M. Metals Handbook, 1939.

Effect of Alloying Elements on the Properties of Steel

When relatively large amounts of alloying elements are added to steel, the characteristic behavior of carbon steels is obliterated. Most alloy steel is medium- or high-carbon steel to which various elements have been added to modify to an appreciable extent its properties, but it still owes its distinctive characteristics to the carbon that it contains. It is not possible to give an average value of the percentage of alloy element required for a given purpose, since they vary in the intensity of their effect, but the range would be from a few hundredths of a percent to possibly as high as 5 percent.

When ready for service, these steels will usually contain only two constituents, ferrite and carbide. The only way that an alloying element can affect the properties of the steel is to change the dispersion of carbide in the ferrite, change the properties of the ferrite, or change the properties of the carbide. The effect on the distribution of carbide is the most important factor, since in sections amenable to close control of structure, carbon steel is only moderately inferior to alloy steel. However, in large sections where carbon steels will fail to harden throughout the section even on a water quench, the hardenability of the steel can be increased by the addition of any alloying element (except possibly cobalt). The effect of the alloying element when dissolved in the austenite is to displace the S curve (Fig. 3) to the right. This permits the hardening of a larger section of alloy steel

elements such as nickel, chromium, manganese, or molybdenum to give sufficient hardenability. In regard to the correct **heat-treatment**, it must be remembered that a carburized steel is a duplex material having a high-carbon case and a low-carbon core with a more or less gradual transition from one to the other. Two critical temperatures are thus involved in the hardening of a carburized part. The temperatures for several representative steels are given in Table 9.

Table 9. Critical Points of Carburized S.A.E. Steels, Deg F

S.A.E. No.	1015	1315	2315	2515	3115	3215	3312	3415	4115	4615	4815	5115	6115	4340

Annealing and Hardening of Carburized Parts. To minimize distortion, a part should be annealed at a temperature 50 F above the carburizing temperature and the rate of cooling from the annealing temperature should be regulated to provide the required structure for best machinability. For **hardening**, there are three treatments in general use. First, a direct quench from the carburizing temperature into a suitable quenching medium. This method was not used until recently except with parts of regular shape because of the danger of cracking and distortion. With the advent of steels *that maintain a fine grain size at carburizing temperatures, distortion is* found to be less by direct quenching than by any other method. A second treatment is to cool slowly from the carburizing temperature, reheat to above the critical of the case, and quench. This facilitates handling of large quantities of carburized parts delivered discontinuously from a batch-type furnace and minimizes the retention of austenite in the high-carbon case. The old "double-quench" method in which the part was slowly cooled from the carburizing temperature, reheated and quenched from above the core critical temperature, then reheated and quenched from above the critical of the case is no longer favored.

Cyaniding. Where it is necessary to have only a superficial hard wear-resisting surface, a rapid method of casehardening is to use a molten cyanide bath. The bath usually consists of sodium cyanide with sodium chloride and sodium carbonate to retard the decomposition of the cyanide. The cyaniding should be carried out at a temperature just above the critical of the core, and the steel should be quenched directly from the cyanide bath. A uniform case depth of around 0.010 in. is obtained in 1 hr in both carbon and low-alloy steels, and besides carbon the case will contain very hard iron nitrides which increase the wear resistance of the surface of the steel part. Cyanide baths are frequently used simply as a heating medium in connection with the hardening of steels to prevent surface decarburisation and produce work with a clean surface.

Nitriding. The introduction of nitrogen into the outer surface of steel parts in order to give an extremely hard, wear-resisting case is called nitriding. The treatment consists in heating steel to a temperature of 950 to 1000 F inside a chamber through which a controlled stream of ammonia gas is passed. The treatment usually lasts 50 to 90 hr depending upon the composition of the steel and the depth to which it is desired to effect nitrification. The nitriding temperature is below the thermal critical range and even below

will have some aluminum added during deoxidation. The presence of finely scattered carbides in the austenite appears to have a similar effect on the austenite grain size, so the elements forming stable carbides will also contribute to the formation of a fine-grained austenite.

In Table 5, a summary of the effects of various alloying elements is given. It must be remembered that this table indicates only the trends of the various elements, and the fact that one element has an important influence on one factor does not prevent it from having an equally strong influence on another one.

Principles of Heat-treatment of Iron and Steel

When heat-treating a steel for a given part, certain precautions have to be taken to develop optimum mechanical properties in the steel. Some of the major factors that have to be taken into consideration are outlined below. For detailed information, reference should be made to the A.S.M. Metals Handbook.

Heating. The first step in the heat-treatment of steel is the heating of the material to above the critical to make it fully austenitic. The **heating rate** should be sufficiently slow to avoid injury to the material through excessive thermal and transformational stresses. In general, hardened steel should be heated more slowly and uniformly than is necessary for soft stress-free materials. Large sections should not be placed in a hot furnace, the allowable size depending upon the carbon and alloy content. For high-carbon steels, care should be taken in heating sections as small as 2 in. diam, and in medium-carbon steels precautions are required for size over 6 in. diam. The **maximum temperature** selected will be determined by the chemical composition of the steel and its grain-size characteristics. In hypoeutectoid steel (below 0.80 percent carbon), a temperature just above the upper critical range is used, and in hypereutectoid steels (above 0.80 percent carbon), a temperature between the lower and the upper critical is generally used so as to avoid heating to high temperatures with consequent grain growth. See Table 6 for heat-treating temperatures for plain carbon steels and Table 7 for approximate critical temperatures of S.A.E. steels. The **time at maximum temperature** should be such that a uniform temperature is obtained throughout the cross section of the steel. Care should be taken to avoid undue length of time at temperature since this will result in undesirable grain growth, scaling, or decarburization of the surface. A practical figure often given for the total time in the hot furnace is ½ hr per in. of cross-sectional thickness. When the steel has attained a uniform temperature, the **cooling rate** must be such as to develop the desired structure: slow cooling rates (furnace or air cooling) to develop the softer pearlitic structures and high

blocks surrounding the bearing. The extent of the heated zone can be so closely controlled that the fillets will remain soft while the bearing surface is hardened, thereby reducing the possibility of fatigue failure without sacrificing wear resistance at the bearing surface.

Commercial Steels

The variety of applications of steel for engineering purposes is due to the wide range of physical properties obtainable by changes in carbon content and heat-treatment. For the A.S.T.M. specifications, see p. 577. Applications of carbon steels are given in Table 11. Carbon steels can be subdivided

Table 11. Applications of Carbon Steels

Percent C	Uses
0.05–0.10	Sheet, strip, tubing, wire, nails
0.10–0.20	Rivets, screws, parts to be casehardened
0.20–0.35	Structural steel, plate, forgings such as camshafts, etc.
0.35–0.45	Machinery steel—shafts, axles, connecting rods, etc.
0.45–0.55	Large forgings—crankshafts, heavy-duty gears, etc.
0.60–0.70	Bolt-heading and drop-forging dies, rails, set screws
0.70–0.80	Shear blades, cold chisels, hammers, pickaxes, band saws
0.80–0.90	Cutting and blanking punches and dies, rockdrills, hand chisels
0.90–1.00	Springs, reamers, broaches, small punches and dies
1.00–1.10	Small springs, lathe, planer, shaper and slotter tools
1.10–1.20	Twist drills, small taps, threading dies, cutlery, small lathe tools
1.20–1.30	Files, ball races, mandrels, drawing dies, razors

roughly into three groups: (1) low-carbon steel, 0.05 to 0.25 percent carbon, where only moderate strength is required together with considerable plasticity; (2) machinery steels, 0.30 to 0.55 percent carbon, which can be heat-treated to develop high strength; and (3) tool steels containing from 0.60 to 1.30 percent carbon. This last range also includes rail and spring steels.

Low-carbon Steels. Of the many low-carbon-steel products, sheet and strip steels are becoming increasingly important. The consumption of steel in the sheet and tin-plate industry in 1937 accounted for approximately 40 percent of the total steel production in the United States, and recent trends would indicate even higher consumption in the future. This increased consumption has been made possible by the development of the continuous sheet and strip rolling mills. Applications in which large quantities of sheet are employed are tin plate for food containers, black, galvanized, and terne-coated sheets for building purposes, and high-quality sheets for automobiles, furniture, refrigerators, and countless other stamped, formed, and welded products. The difference between sheet and strip is based on width and is arbitrary. The difference between hot- and cold-rolled products is that in hot rolling the steel is heated before the final rolling and in cold rolling it is not. Cold working produces a better surface finish, increases the mechanical properties, and permits the rolling of thinner gage material than hot rolling. Approximate mechanical properties of cold-rolled strip steel are given in Table 12.

Sheets for deep-drawing applications must be dead soft so as to have a maximum amount of plasticity. They must also have a relatively fine grain size, since a large grain size will cause a rough finish, an "orange peel" effect, on the deep-drawn article. It is necessary to eliminate the sharp yield point that is characteristic of low-carbon steel so as to prevent sudden local elongations in the sheet during forming which result in strain markings

Certain oils are satisfactory but are incapable of hardening shallow-hardening steels of substantial size. A change in steel composition is required with a change from water to an oil quench. Quenching in oil does not entirely prevent distortion. When the degree of distortion produced by oil quenching is objectionable, recourse is taken to air hardening. The cooling rate in air is very much slower than in oil or water, so an exceptionally high alloy content is required. This means that a high price is paid for the advantage gained, both in terms of metal cost and loss in machinability, though it may be well justified when applied to expensive tools. In this case, danger of cracking is negligible.

Liquids for Quenching Shallow-hardening Steels. Shallow-hardening steels require extremely rapid surface cooling in the quench particularly in the temperature range around 1020 F. A submerged water spray will give the fastest and most reproducible quench practicable. Such a quench is limited in application to simple short objects which are not likely to warp. Because of difficulty in obtaining symmetrical flow of the water relative to the work, the spray quench is conducive to warping. The ideal practical quench is one that will give the required surface cooling without agitation of the bath. The addition of ordinary salt, sodium chloride, greatly improves the performance of water in this respect, the best concentration being around 10 percent. Most inorganic salts are effective in suppressing the formation of vapor at the surface of the steel and thus aid in cooling steel uniformly and eliminating the formation of soft spots. To minimize the formation of vapor, water-base quenching liquids must be kept cold, preferably under 70 F. The addition of some other soluble materials to water such as soap is extremely detrimental because of increased formation of vapor.

Liquids for Quenching Deep-hardening Steels. When oil quenching is required, use a steel of sufficient alloy content to produce a completely martensitic structure at the surface over the heaviest section of the work. To minimize the possibility of cracking, especially when hardening tool steels, keep the quenching oil warm, preferably between 100 and 150 F. If this expedient is insufficient to prevent cracking, the work may be removed just before the start of the hardening transformation and cooled in air. Whether or not transformation has started can be determined with a permanent magnet, the work being completely non-magnetic before transformation if completely hardened by the quench.

The cooling characteristics of quenching oils are difficult to evaluate and have not been satisfactorily correlated with the physical properties of the oils as determined by the usual tests. The standard tests are important with regard to secondary requirements of quenching oils. Low viscosity assures free draining of oil from the work and therefore low oil loss. A high flash and fire point assures a high boiling point and reduces the fire hazard which is increased by keeping the oil warm. A low carbon residue indicates stability of properties with continued use and little sludging. The steam-emulsion number should be low to assure low water content, water being objectionable because of its vapor film forming tendency and high cooling power. A low saponification number assures that the oil is of mineral base and not subject to organic deterioration of fatty oils which give rise to offensive odors. Viscosity index is a valuable property for maintenance of composition.

Effect of the Condition of Surface. The factors that affect the depth of hardening are the hardenability of the steel, the size of specimen, the

Casehardening. The production of articles having a soft ductile interior and a very hard surface can be accomplished by carburizing a low-carbon steel at an elevated temperature and then quenching. The process of carburizing followed by hardening is known as casehardening.

Carburizing methods can be divided into three groups: pack carburizing where a solid carburizing agent is used, gas carburizing, and liquid carburizing. In **pack carburizing**, the usual compound contains 20 percent metallic carbonates (mostly barium carbonate) bound to a hardwood charcoal by the use of oil, tar, or molasses. Sometimes up to 20 percent coke is added in order to increase the rate of heat transfer. Before using again, used compound should have some new compound added to make up for loss of carbonates, powdering of the compound, and burning of the charcoal and coke. One part new compound is often added to 3 parts used compound, but with care in handling this can be cut down to 1 part new to 5 parts old.

Carburizing boxes are usually made from a high-nickel-chromium heat-resisting alloy. Cast-steel or welded-steel plate boxes may be substituted when the boxes are used infrequently or when the work being carburized is large and nonsymmetrical. Work should be packed with its longest dimension vertical, and the minimum amount of compound should be used so as to decrease the heating time. Normal **carburizing temperatures** are around 1700 F, but for nickel steels a temperature of 1650 F is used and for shallow-case depth, temperatures as low as 1550 F. It is difficult to prevent variations of 0.010 in. in case depth, and therefore it is standard practice to specify case depths of at least 0.025 in. when pack carburizing. By using a minimum of carburizing compound, the over-all carburizing time for a case of 0.040 to 0.050 in. will be about 9 hr. The pack method of carburizing is adaptable to both batch and continuous furnace operation; warping is held to a minimum. The main disadvantages are the time consumed in heating the charge and the high labor cost of packing and unpacking.

Gas carburizing is being developed and may eventually replace other methods. Low labor costs and automatic quenching reduce the operating costs to a low figure, but the high initial investment is justified only by large units operating at high output. The carburizing gases used are carbon monoxide, methane, ethane, and propane. The hydrocarbons will break down, if undiluted, liberating an excessive amount of carbon in the form of soot on all exposed surfaces. By diluting with gases such as nitrogen and hydrogen, the amount of free carbon deposit will be decreased. Cases of 0.040 to 0.050 in. can be obtained in 4 hr at 1700 F. By suitable adjustment of time, temperature, and gas composition, the surface carbon content and the carbon gradient can be varied to meet almost any requirement.

Liquid carburizing is done in activated baths of calcium cyanamid, sodium or potassium cyanide, and controlling chemicals which govern the decomposition of the cyanides. The baths are operated at between 1500 and 1650 F, and cases of 0.020 in. are obtained in 90 min. For case depths of more than about 0.030 in. it is more economical to use either pack or gas carburizing. The process is extremely flexible, easily controlled, and particularly well adapted to small units. With continuous operation and automatic quenching, labor costs are low.

The type of **steel for carburizing** will depend upon section and distortion limits of the finished part and the stresses to which it will be subjected. Plain carbon steels of between 0.15 and 0.25 percent carbon are used extensively and after heat-treatment will develop core strengths as high as 100,000 lb per sq in. To develop higher core strengths, it is necessary to have alloying

manganese sulphide inclusions causing the chips to break short on machining. Manganese and phosphorus harden and embrittle the steel which also contributes toward free machining. The familiar steels S.A.E. 1112 and X1112 known as **Bessemer screw stock** have excellent machinability. Steels having a small percentage of lead (about 0.25) have good machinability. These **leaded steels** increase the machinability of free-cutting steels more

the usual tempering temperature so that the mechanical properties of the previously heat-treated core metal are not affected by nitriding. The big advantage of nitriding is that hardening is accomplished without a quenching operation, so that complicated shapes and articles of uneven cross section can be treated with safety. The steel used is usually heat-treated before machining, rough-machined, given a heat-treatment at the nitriding temperature without ammonia in order to produce whatever slight distortion is likely to occur, then the part is finish machined and nitrided. Besides wear resistance, nitriding aids in the retention of hardness at elevated temperatures and to some extent increases the resistance to corrosion. The disadvantages of nitriding include high cost, time of operation, and expert attention.

Stock for Nitriding. A series of steel alloys containing aluminum, known as **Nitralloy**, give the best results in the nitriding process. The compositions of the most commonly used nitriding steels are given in Table 10 (A.S.M. Metals Handbook, 1939).

Flame hardening is the local heating of steel above the critical temperature so that on subsequent quenching a hardened layer will be produced. The depth of the flame-hardened layer will vary from $\frac{1}{16}$ to about $\frac{1}{4}$ in. depending upon the service requirements. For local hardening or for hardening the surface of large steel parts, this method has been very useful, especially since distortion of the part is kept to a minimum. The chemical analysis of the steel has to be such as to respond readily to heat-treatment. For plain carbon steels, the carbon content should be between 0.35 to 0.70 percent, although steels with higher carbon content may be flame hardened if care is taken to prevent surface cracking. To obtain satisfactory results by flame hardening, the character of the flame, its distance from the surface of the work, its speed of travel, and the timing of the quench must all be under perfect control. After quenching, tempering is essential to relieve the stresses, a temperature of 400 F usually being sufficient. Flame hardening may be adapted to castings, forgings, or rolled sections irrespective of size. Typical applications are for the hardening of gear teeth, cams, wheel treads, rail ends, and many machine parts.

Local hardening can also be accomplished by local heating with electricity. Resistance heating is useful in hardening local sections of some forgings and castings, but in general its principal application is for heating parts having a uniform cross section. Induction heating is well adapted for the surface hardening of cylindrical parts. Crankshaft bearings are hardened by the patented "Tocco" process by applying a high-frequency current to the bearing section for a few seconds. When the steel is heated to the desired depth, water is sprayed on the heated surface through holes in the inductor

called **stretcher strains** or **Lüders' lines.** The sharp yield point can be eliminated by cold working (Fig. 1), a reduction of only 1 percent in thickness usually being sufficient. This cold reduction is usually done by cold rolling, known as **temper rolling,** followed by alternate bending and reverse bending in a roller leveler. Temper rolling must always precede roller leveling because soft-annealed sheets will "break" (yield locally) in the roller leveler. An important phenomenon in these temper-rolled low-carbon sheets is the return of the sharp yield point after a period of time. This is known as **aging** in steel. The return of the yield point is accompanied by an increase in hardness and a loss in ductility. Greater reductions by temper rolling decrease the rate of the aging process, and an increase in temperature greatly increases its rate. It is therefore necessary to fabricate the sheets soon after temper rolling in order to avoid stretcher strains. Recently, non-aging sheets have been developed by using killed steels, but these will probably be used only in special applications because of the added cost.

Table 12. Approximate Physical Properties for Various Tempers of Cold-rolled Strip Steel

(A.S.T.M. Specifications for Cold-rolled Strip: A109-38)

Grade or temper	Rockwell hardness B scale, 1/16 in. ball 100 kg load	Depth of cup for 0.050 in. thickness of strip, mm[a]	Tensile strength,[b] kips	Elong in 2 in. for 0.050 in., thickness of strip,[c] percent	Remarks
No. 1 hard	90 ± 6[d]	6-7	80 ± 12	3 ± 2	[e]
No. 2 half hard	80 ± 5	7-8	64 ± 8	9 ± 5	[f]
No. 3 quarter hard	69 ± 5	8-9	54 ± 6	20 ± 7	[g]
No. 4 soft or planished	58 ± 6	9-10½	48 ± 5	30 ± 6	[h]
No. 5 dead soft	45 ± 7	10-10½ 10-11½	44 ± 4	39 ± 6	[i]

[a] Cup depth varies with thickness of strip. For grade 5, dead soft temper, the depth is given approximately by the formula $D = 10.5 \text{ mm} + 6.4 \log t$ (t = thickness in mm). Other tempers vary in a similar way.

[b] Tensile properties are based on the standard tension test specimen for sheet metals, Fig. 7, A.S.T.M. E 8, 1939, Standards, Part I, p. 756.

[c] Elongation in 2 in. varies with the thickness of strip. For grade 5, dead soft temper, the percentage elongation $= 41 + 10 \log t$ (t = thickness in mm). Other tempers vary in a similar way.

[d] For cold strip 0.069 in. and thinner in thickness the Rockwell B hardness range is 96 ± 6, with corresponding increase in tensile strength and drop in depth of cup test.

[e] Intended for flat blanking only.

[f] Intended for easy bending up to 90 deg across the grain. (No bending along the grain.)

[g] For shallow drawing and stamping, where a very smooth surface is required. Bends 180 deg across the grain. Bends up to 90 deg along the grain.

[h] For fairly deep drawing where no sign of surface strain is permissible. Bends 180 deg both ways of the grain.

[i] For deep drawing where slight stretcher strains are permissible. Also for drifting. (Erroneously called "extrusion.") Bends 180 deg both ways of the grain.

Other important low-carbon steel products are plates, structural shapes, tubing, pipe, and wire. Boiler plate, rivets, and tubes are usually in the

range of 0.15 to 0.30 percent carbon. Structural steel has approximately the same carbon range, although some higher carbon steel shapes are sometimes used in bridges and heavy machinery. A special group of low-alloy high-strength steels has recently been developed for the transportation industries where a high ratio of strength to weight is required. Although these steels have a lower strength-weight ratio than high-strength stainless steels and light aluminum alloys, they are used to a large extent in the construction of passenger, freight, and tank cars, truck and trailer bodies, unloading buckets, and similar applications. In general, the low-alloy high-strength steels have a yield point of 50,000 and a tensile strength of 90,000 lb per sq in. and the ductility will be only slightly lower than that of mild steel. These steels can be formed either hot or cold, welded, flame cut, punched, reamed, and machined. In welding or flame cutting, precautions must usually be taken against hardening with resultant loss in ductility. These steels are definitely more difficult to machine than structural carbon steels, higher tool pressures being necessary so that tool speeds should be reduced and a cooling agent used. For detailed information on these steels, see *Metals and Alloys*, **9**, 1938, p. 243. Table 13, taken from this article, lists the trade names and manufacturing companies and gives approximate compositions and mechanical properties of the different steels.

Machinery Steels. The S.A.E. has specifications (S.A.E. Handbook) for steels that cover the requirements in the automotive industry, and these specifications have been widely adopted by industry in nearly all fields of mechanical manufacturing both in America and abroad. A numerical index, which in general consists of four digits, is used to identify the composition of the S.A.E. steels. The first digit indicates the alloy type, and, in the simple alloy steels, the second digit indicates the approximate percentage of the predominant alloying element. The last two digits indicate the average carbon content in "points," or hundredths of 1 percent. Thus 2340 indicates a nickel steel of approximately 3 percent nickel (3.25 to 3.75) and 0.40 percent carbon (0.35 to 0.45); and 71360 indicates a tungsten steel of about 13 percent tungsten (12 to 13) and 0.60 percent carbon (0.50 to 0.70). In some instances, it has been found necessary to depart from this system in order to avoid confusion. The prefix X is used in numerous instances to denote variations in the range of elements. The prefix T is used with the manganese steels (1300 series) to avoid confusion with steels of somewhat different manganese range that have been identified by the same numericals but without the prefix.

Specific applications of S.A.E. steels cannot be given, since the selection of a proper steel for a given part must depend upon an intimate knowledge of factors such as the availability and cost of the material, the detailed design of the part, and the severity of the service to be imposed, machinability, size, etc. To a large extent, the mechanical properties desired in the part to be heat-treated will determine the carbon and alloy content of the steel. Table 15 gives a résumé of mechanical properties of typical S.A.E. steels as given in the S.A.E. Handbook, 1939 (for sizes up to 1½ in. diam). Table 16 gives the effect of mass on the mechanical properties of heat-treated steels.

The low-carbon S.A.E. steels are used for carburized parts (see p. 553), cold-headed bolts and rivets, and for similar applications where high quality is required. An important series of steels is the S.A.E. low-carbon free-cutting steels for high-speed screw-machine stock and other machining purposes. These steels have high sulphur present in the steel in the form of

Table 18. Classification of American Tool Steels.—(*Continued*)
(Adapted from Gill, "Tool Steels," *Metal Progress*, Oct., 1938)

TUNGSTEN FINISHING TOOL STEELS AND DRAWING DIES
(Brittle but intensely hard and keen edges for cutting hard materials)
Water hardening; medium wear resistance; low toughness; high warpage; no red hardness; deep hardening

C	W	Cr	Remarks	
1.20–1.40	5.00–6.00	....	Slightly better wear resistance than lower tungsten	High movement; best for drawing dies that must be rehardened after wear
1.20–1.40	3.00–5.00	....	Slightly tougher than higher tungsten	
1.20–1.40	4.00–6.00	0.40–0.80	Chromium improves heat treatability and reduces volume change	
1.20–1.40	4.00–6.00	1.00–1.50		

SILICON-MANGANESE PUNCH AND CHISEL STEELS
(A water hardening and inexpensive steel for cold cutting)
Medium wear resistance; medium toughness; medium warpage; medium hot hardness medium deep hardening

C	Si	Mn	Cr	Mo	V	Remarks
0.50–0.60	1.80–2.20	0.60–0.90	....	....	....	Spring steel analysis; all high-silicon steels liable to soft skin
0.60–0.75	1.70–2.25	0.70–0.90	....	....	....	More carbon gives higher hardness
0.50–0.60	1.75–2.25	0.70–0.90	0.20–0.35	....	0.15–0.30	Alloys increase hardenability and refine grain
0.50–0.60	1.75–2.25	0.70–0.90	....	0.40–0.60	....	Molybdenum greatly increases hardenability
0.50–0.60	0.75–1.25	0.35–0.60	0.20–0.40	0.40–0.60	....	Low silicon reduces brittleness and wear resistance

HIGH CARBON, HIGH CHROMIUM PUNCH AND DIE STEELS
(Durable rolls, mandrels, punches, dies, and shears for cold work)
High wear resistance; low toughness; low warpage; high hot hardness; deep hardening, difficultly machinable

C	Cr	V	Mo	Co	Ni	Remarks
		Oil Hardening Types ("Non-Deforming")				
2.25–2.45	12.00–14.00	....	....	....	....	
2.10–2.20	12.00–14.00	0.75–1.00	....	....	....	Somewhat tougher
2.15–2.25	12.00–14.00	....	....	....	0.50–0.75	Slightly air hardening; most difficult to machine
2.15–2.25	12.00–13.00	0.75–1.00	....	0.60–1.00	....	Slightly red hard
		Air Hardening Types (Tougher Than Above; and Deform Less in Hardening)				
1.40–1.60	12.00–13.00	....	0.50–0.60	3.00–4.00	....	Red hard properties. Good for cutting tools on non-ferrous materials
1.50–1.70	16.50–18.00	....	....	....	....	Liable to harden non-uniformly
1.50–1.60	12.00–13.00	....	0.80–1.00	....	....	
1.50–1.60	12.00–13.00	0.80–1.00	0.75–0.90	0.40–0.60	....	Vanadium imparts greater toughness
1.40–1.55	12.00–13.00	0.80–1.00	0.75–0.90	....	0.60–0.80	Most difficult to machine

CHROMIUM DIE STEELS FOR HOT WORK
(Gripper, bending, and heading dies for light work up to 600 F.)
Air or oil hardening, medium wear resistance and toughness; low warpage; medium hot hardness; deep hardening

C	Cr	Mo	Remarks
0.85–1.00	3.75–4.00	....	Usually quenched in light air blast
0.85–1.00	3.25–3.75	....	Lower chromium reduces cracks during oil quenching
0.65–0.75	3.75–4.25	....	Oil quenching (lower carbon) but not so rigid at 500 F
0.85–1.00	3.75–4.25	0.40–0.00	Best air hardener

Silicon range of all S.A.E. basic open-hearth alloy steels shall be 0.15 to 0.30. For electric and acid open-hearth alloy steels, the silicon content shall be 0.15 min.

than that of other grades. Cold drawing improves the machinability of free-cutting steels; they are usually supplied cold-drawn.

Cold-finished carbon-steel bars are used for parts such as bolts, nuts, typewriter and cash-register parts, motor and transmission power shafting, piston pins, bushings, oil pump shafts and gears, etc. Average mechanical properties of cold-drawn steel are given in Table 17. Besides increasing the mechanical properties, cold-finished steel has better machining properties than hot-rolled products. The surface finish and dimensional accuracy are also greatly improved by cold finishing.

Forging steels, between 0.30 and 0.40 percent carbon, are used for axles, bolts, pins, connecting rods, and similar applications. These steels are readily forged and, after heat-treatment, develop considerably higher mechanical properties than low-carbon steels. For heavy sections, where high strength is required, such as in crankshafts and heavy duty gears, the carbon is increased to 0.40 to 0.50 percent (S.A.E. 1045).

Tool Steel. Tool steels can be subdivided into four classifications: (1) plain carbon steels, (2) oil-hardening steels, (3) semi-high-speed steels, and (4) high-speed steels.

roughing operations. Molybdenum may be substituted for part of the tungsten to reduce cost and to give increased toughness.

Very high heating temperatures are required for the heat-treatment of high-speed steel. The steel should be heated slowly to 1600 F, held until a uniform temperature is reached, then heated rapidly to 2300 F by transferring to another furnace held at the latter temperature. It is held in the furnace only for the time necessary to bring it to temperature, then is quenched in warm oil or in an air blast. The high-speed steel should then be tempered at about 1100 F to increase the toughness; owing to a secondary hardening effect, the hardness of the tempered steel may be higher than as quenched. In general, cobalt high-speed steels require higher, and molybdeaum steels lower, quenching temperatures than the 18-4-1. A list of the more common American tool steels is given in Table 18.

Spring Steel. *For small springs, steel is often supplied to spring manufacturers in a form that requires no heat-treatment except perhaps a low-temperature anneal to relieve forming strains.* Types of previously treated steel wire for small helical springs are **music wire** which has been given a special heat-treatment called patenting and then cold-drawn to develop a high yield strength, **hard-drawn wire** which is of lower quality than music wire since it is usually made of lower grade material and is seldom patented, and **oil-tempered wire** which has been quenched and tempered. The wire usually has a Brinell hardness between 352 and 415, although this will depend on the application of the spring and the severity of the forming operation. Steel for small flat springs has either been cold-rolled or quenched and tempered to a similar hardness.

Steel for both helical and flat springs which is hardened and tempered after forming is usually supplied in an annealed condition. Plain carbon steel is satisfactory for small springs; for large springs it is necessary to use alloy steels such as chrome-vanadium or silicon-manganese steel in order to obtain a uniform structure throughout the cross section. Table 19 gives the chemical composition and heat-treatment of several spring steels (see p. 549 for further information on heat-treatment). It is especially important for springs that the surface of the steel be free from all defects.

Table 19. Chemical Composition and Heat-treatment of Spring Steels

Steels	Composition, percent					Heat-treatment temperatures, deg F		
	C	Mn	Si	Cr	V	Normalizing	Quenching	Tempering

Plain carbon tool steels, containing 0.60 to 1.40 percent carbon, are widely used on account of their low cost and excellent properties. For tools such as files, twist drills, threading dies, and small taps for which the primary requirement is a high hardness, a carbon content of 1.20 percent or higher is necessary. In tools subjected to shock, such as shear knives, chisels, hammers, and forging dies, the carbon content has to be kept below about 0.80 percent. For applications requiring both a high hardness and considerable toughness, the carbon content will be around 1 percent. Carbon steels do not have the ability to retain their hardness at the elevated temperatures developed in the tip of metal-cutting tools when operating under severe conditions. Carbon steels are liable to crack or warp on hardening whenever the tool has an intricate shape.

The **oil-hardening steels**, sometimes called non-deforming steels, have sufficient alloy content to be hardened on quenching in oil; distortion and cracking is therefore minimized. They usually contain up to 1.75 percent manganese with small percentages of chromium, molybdenum, vanadium, or tungsten and have the same general performance characteristics as plain carbon tool steels.

Semi-high-speed steels can operate at higher temperatures than carbon steels without losing their hardness in consequence of fairly high proportions of tungsten and chromium. The alloy carbides resist the tempering effect of high tool temperatures and also contribute to the abrasion resistance of the steel. On account of the high alloy content, the steels can be hardened in oil and thus are not liable to crack or warp on hardening.

High-speed steels retain considerable hardness at a red heat. A commonly used high-speed steel has 18 percent tungsten, 4 percent chromium, and 1 percent vanadium (known as 18-4-1 high-speed steel). Cobalt, sometimes added as an alloying element, improves the cutting qualities for

C. Have high creep strength up to 1200 F. Toughness impaired in relatively high carbon alloys by service at 800 to 1500 F.

Hot-working Qualities. A. Readily forged, pierced, or rolled at 2000 to 1700 F. Preheat and soak stock at 1600 F. Plain chromium alloys air harden on cooling.

B. May be forged, rolled, or pierced. Should be heated quickly. Forge from 2200 F down to 1750 F. On last heat continue cold working to 1400 F to refine grain. Alloys do not air harden.

C. May be forged, rolled, or pierced. Preheat and soak at 1600 F, heat quickly to 2200 F, forge down to 1850 F. Hot short range: 1800 to 1300 F. Alloys do not air harden.

Cold-working Qualities. A. Low carbon varieties can be easily cold drawn into wire, cold rolled, bent, formed, upset, coined, and deep drawn.

B. Can be cold drawn into wire, cold rolled, bent, formed, upset, coined, and deep drawn, especially when warm (300 to 500 F).

C. Can be cold drawn into wire, cold rolled, bent, formed, upset, coined, and deep drawn. Work harden twice as rapidly as Groups A and B.

Machinability. A. Machine satisfactorily with properly designed tools when heat treated to 200 to 250 Brinell. *Free-cutting grade contains zirconium sulphide.*

B. Machine satisfactorily with properly designed tools. Cold working and high sulphur improve machinability.

C. Most difficult of all. Use sharp tool having greater top rake than usual, and cut continually. Free-cutting grade contains selenium and phosphorus.

Riveting. A. Make excellent cold rivets. Not recommended for hot rivets driven above 1500 F, on account of air hardening.

B. Extra precautions required to avoid brittle rivets. Conical heads should be cold upset on ground bars; rivets driven at 1425 F into chamfered holes.

C. Excellent for either hot or cold rivets. Hot rivets may be driven at a high temperature (1900 F).

Welding Properties. A. Can be welded with gas, electric arc, or resistance. Weld air hardens. Little grain growth.

B. Can be welded. Anneal at 1450 F to reduce embrittlement alongside weld. Those metals subject to grain growth are brittle adjacent to the weld. Those metals not subject to grain growth yield satisfactory welds.

C. Can be welded with gas, electric arc, or resistance, if carburization is avoided. Weld does not air harden and is very tough. Only the relatively low carbon of "stabilized" metal should be welded if article must resist severe corrodents.

Corrosion Resistance. A. Very satisfactory for resisting weather, water, steam, and many organic and inorganic corrodents when chromium is 11.5 percent or more. If carbon is relatively high, metal must be hardened and tempered (below 1000 F).

B. Possess corrosion resisting properties superior to Group A. Especially good for nitric and other oxidizing acids.

C. Corrosion resistance depends largely upon total alloy content. This group will resist nearly all corrodents measurably better than Groups A and B. Especially good for organic acids. Severe pitting may occur in some stagnant solutions, under particles of foreign matter.

Scale Resistance. A. Useful for continuous temperatures up to 1200 F, and in some services up to 1500 F.

B. Superior to Group A, especially when chromium is above 25 percent; then resist reducing atmospheres up to 2100 F, oxidizing up to melting points, and sulphur gases up to 1800 F.

C. Excellent where combination of high temperature and corrosion is to be met. Low nickel alloys required to resist sulphurous gases.

Group A (Martensitic). The hardenable alloys were the first stainless steels to be developed and, because of their high hardness and stain resisting properties, are used extensively for table cutlery, pocket knives, surgical and dental instruments, springs for high-temperature operation, ball valves and seats, and similar applications. The highest grade of stainless cutlery steel has 0.70 percent C and 16 percent Cr. Forging and annealing treatments are given in Table 20. The proper hardening range depends on

Table 18. Classification of American Tool Steels

(Adapted from Gill, "Tool Steels," *Metal Progress*, Oct., 1938)

GENERAL PURPOSE CARBON TOOL STEELS

Water hardening; low wear resistance; high warpage; no red hardness; shallow hardening

C	Si	Mn	S	P	V	Common Uses
0.60–1.25 [a]	0.15–0.50	0.10–0.35	0.03 max.	0.03 max.	[b]	Almost universal;[c]

CHROMIUM-VANADIUM OR LOW CHROMIUM TOOL STEELS

(Substitutes for carbon tool steels)

Mostly water hardening; low wear resistance; high warpage; no red hardness; medium deep hardening

C	Si	Mn	Cr	V	Remarks
0.50–1.40	0.15–0.50	0.10–0.35	0.10–0.25	....	Chromium corrects tendency toward soft spots
0.50–1.40	0.15–0.50	0.10–0.35	0.25–0.50	....	More intense hardness
0.50–1.40	0.15–0.40	0.10–0.35	0.60–1.20	0.10–0.20	Water hardening } Very tough in low-carbon ranges
0.50–1.40	0.15–0.40	0.40–0.60	0.60–1.20	0.10–0.20	Oil hardening }

HIGH CARBON, LOW TUNGSTEN TOOL AND DIE STEELS

(Finishing tools for hard steels or non-ferrous alloys)

Oil hardening; medium wear resistance; medium toughness; low warpage; no red hardness; medium deep hardening

C	Si	Mn	Cr	W	V (Optional)	Remarks
0.90–1.10	0.20–0.40	0.15–0.30	....	1.00–1.50	....	} Somewhat erratic in heat treatment
1.15–1.25	0.20–0.40	0.15–0.30	....	1.75–2.50	0.10–0.25	}
0.90–1.10	0.20–0.40	0.15–0.30	0.35–0.75	1.50–2.50	0.10–0.25	Water hardening } more dependable
1.15–1.30	0.20–0.40	0.15–0.30	0.35–0.75	1.50–2.50	0.10–0.25	Oil hardening }

MANGANESE OIL-HARDENING DIE STEELS ("NON-DEFORMING")

(General purpose tools and especially dies, punches, and broaches)

Oil hardening; low wear resistance; medium toughness; low warpage; no red hardness; medium deep hardening

C	Si	Mn	Cr	W	Mo	V	Remarks
0.85–0.95	0.20–0.40	1.50–1.75	....	....	....	0.10–0.25	More subject to grain growth
0.85–1.00	0.20–0.40	1.15–1.45	0.30–0.60	0.30–0.60	....	0.10–0.25	Corrects above, but hardness is lower
0.85–1.00	0.20–0.40	1.35–1.65	....	....	0.20–0.35	0.10–0.25	Attains highest hardness
0.90–1.00	0.20–0.40	0.90–1.15	0.50–0.90	....	....	....	Least susceptible to hardening cracks

TUNGSTEN ALLOY CHISEL AND PUNCH STEELS

(Oil hardening steels; shears and battering tools for cold metal; heading dies)

Medium wear resistance; high toughness; low warpage; medium red hardness; medium deep hardening

C	W	Cr	V	Si	Remarks
0.45–0.60	0.75–1.25	0.75–1.25	....	1.00–1.50	Good wear resistance but somewhat brittle
0.45–0.60	1.50–2.00	0.75–1.25	....	1.00–1.50	Higher tungsten improves wear resistance
0.45–0.60	1.00–1.75	0.50–1.00	....	....	Low silicon increases toughness 25 percent
0.40–0.55	1.75–2.25	0.75–1.25	0.10–0.30	....	} Most popular analyses, tough and fine grained
0.55–0.65	1.75–2.25	0.75–1.25	0.10–0.30	....	}

[a] Usually subdivided by 0.10 percent steps; for instance, 0.65 to 0.75 percent, 0.75 to 0.85 percent, etc.

[b] Plain carbon steels have no vanadium; carbon-vanadium tool steels may have from 0.08 to 0.40 percent vanadium, depending on grade.

[c] In lower carbon ranges, the steels make shear blades, hammers, striking dies, rock drills. In medium ranges of carbon, the steels make chisels, smith's tools, dies, and cutters for machine tools. In the higher ranges of carbon are small cutters, woodworkers' tools, and cutlery.

composition and size, but, in general, the higher the quenching temperature, the harder the article. Oil quenching is preferable, but with thin and intricate shapes, which might warp on quenching, satisfactory hardening is obtained by cooling in air. Tempering around 900 F does not lower the tensile strength, and in this condition the steel shows remarkable resistance to weathering, to attack by fruit and vegetable acids, lye, ammonia, and other corrosive agents to which cutlery may be subjected.

Group B (Ferritic). This group is frequently called stainless iron because of its low carbon content. The alloys possess considerable ductility, ability to be worked hot or cold, excellent corrosion resistance, and are relatively inexpensive. Although these low-carbon chromium alloys cannot be hardened by heat-treatment, they can be hardened to a considerable extent by cold working. Alloys containing 16 to 18 percent Cr are probably the most useful of the straight chromium steels on account of their forming and medium-deep-drawing properties. They are used extensively for kitchen equipment, dairy machinery, interior decorative work, automobile trimmings, and for chemical equipment to resist nitric acid corrosion.

For resisting oxidizing conditions at high temperatures, the Cr content is increased to between 25 and 30 percent. These alloys are useful for all types of furnace parts not subjected to high stress. Since the oxidation resistance is independent of carbon content, soft forgeable alloys low in carbon can be rolled into plates, shapes, and sheets, and hard and wear-resistant castings can be made from higher carbon non-forgeable alloys. The mechanical properties of 12, 17, and 27 percent Cr low-carbon alloys are given in Table 20.

Group C (Austenitic). The addition of substantial quantities of Ni to the high-chromium alloys stabilizes the austenite to such an extent that they are austenitic at room temperature. They cannot be hardened except by cold working, although some excellent properties can be obtained in this manner. Table 21 gives mechanical properties of several austenitic stainless steels. These alloys are highly resistant to many acids including hot or cold nitric acid and at temperatures above 1200 F are stronger and scale less than any of the plain chromium alloys. They are useful for parts subjected to severe stress at elevated temperatures. The most common composition is 18 Cr and 8 Ni (known as 18–8), although many modifications have been developed for special purposes. Tungsten and molybdenum increase the strength at elevated temperatures, silicon and aluminum improve the resistance to scaling, and selenium and sulphur are sometimes added to improve the machinability.

The austenitic stainless steels are not highly resistant to hot sulphurous gases and are sometimes subject to embrittlement and intergranular corrosion. Normal corrosion resistance can be restored by heating the steel above 1700 F and cooling rapidly. When titanium or columbium is added to a low carbon 18–8, the steel is immune to this intergranular attack.

Alloy steels containing 5 percent Cr are used extensively as seamless tube in the oil and power industries because of their low cost and moderate resistance to corrosion. These steels usually contain about 0.5 percent Mo to aid in their resistance to creep at elevated temperatures. Table 20 gives their mechanical properties. Another chromium steel of commercial importance is **silcrome** (0.45 C, 3.25 Si, 9 Cr) used principally for gas-engine exhaust valves. It has a high transformation point, has considerable hardness at operating temperatures, and resists the corrosion and erosion of hot gases.

Table 18. Classification of American Tool Steels.—(*Continued*)
(Adapted from Gill, "Tool Steels," *Metal Progress*, Oct., 1938)

TUNGSTEN DIE STEELS FOR HOT WORK
(Blanking, forming, extrusion, and casting dies to work up to 1100 F.)
Air or oil hardening; medium wear resistance; medium toughness; low warpage; high red hardness; deep hardening

C	W	Cr	V	Remarks
0.25–0.35	8.00–10.00	2.50–3.50	0.30–0.60	In most general use; serviceable up to 1000 F
0.35–0.45	8.00–10.00	2.50–3.50	0.30–0.60	Higher carbon gives higher hardness
0.40–0.50	9.00–12.00	1.25–1.75	....	Chromium lowered to increase toughness
0.25–0.35	12.00–16.00	2.50–3.25	0.30–0.60	Increased tungsten raises serviceability to 1100 F
0.35–0.50	12.00–16.00	2.50–3.25	0.30–0.60	Hardenability and brittleness rise with carbon con-
0.50–0.60	12.00–16.00	2.50–3.25	0.30–0.60	tent
0.50–0.60	17.00–19.00	3.00–4.50	0.60–1.20	Low-carbon, high-speed steel

TUNGSTEN-CHROMIUM STEELS FOR HOT WORK AND DIE-CASTING DIES
Air or oil hardening; medium wear resistance; good toughness; low warpage; high red hardness; deep hardening

C	W	Cr	V	Mo	Si	Remarks
0.40–0.50	6.50–7.50	6.50–7.50	0.20–0.60	....	0.30–0.80	Maximum alloy for hottest services (1000 F)
0.35–0.45	5.50–6.50	5.00–6.00	....	....	0.30–0.80	Tougher
0.30–0.40	0.75–1.25	4.50–5.00	....	1.00–1.50	0.80–1.00	Less expensive substitute
0.35–0.40	....	4.50–5.00	....	1.00–1.50	0.80–1.00	Properties similar to steel above

HIGH SPEED STEELS
(Cutting tools of all types; tools for severe hot work)
Air or oil hardening; high wear resistance; low toughness; low warpage; high red hardness; deep hardening

C	W	Cr	V	Mo	Co	Remarks
			Conventional Types			
0.65–0.75	17.00–19.00	3.50–4.50	0.75–1.25	....	....	Most used; brittleness and cutting properties vary directly with carbon content
0.65–0.75	19.00–21.00	3.75–4.50	0.75–1.25	....	....	Better cutting ability but more brittle
0.75–0.85	17.00–19.00	3.50–4.50	1.75–2.25	0.40–0.90	....	Best cutting ability; excellent for finishing cuts
0.55–0.75	13.00–15.00	3.50–4.50	1.75–2.25	....	....	Roughing tools; somewhat erratic in hardening
			Molybdenum High Speed Steel			
0.60–0.85	1.00–2.50	3.50–4.50	0.75–1.25	6.00–8.00	....	Less expensive; "strategic" alloying element used
0.70–0.90	....	3.50–4.50	1.75–2.50	6.00–9.00	....	Improved by high vanadium content
			Cobalt High Speed Steel			
0.65–0.80	17.00–19.00	3.50–4.50	0.75–1.25	....	3.50–5.00	For cutting hard, gritty or tough materials
0.65–0.80	17.00–19.00	3.50–4.50	1.50–2.25	0.50–1.00	6.00–9.00	Cutting ability varies as total alloy content
0.65–0.80	18.00–21.00	3.50–4.50	1.75–2.25	0.50–1.00	10.00–13.00	Maximum alloy to be forgeable
0.65–0.80	12.00–15.00	3.50–4.50	1.75–2.25	....	5.00–8.00	Good service on special jobs

Silcrome is being replaced by austenitic steels containing silicon and tungsten in heavy-duty engines, since it does not retain its hardness at elevated temperatures or resist scaling as well as the austenitic steels.

Special-property Alloys

Iron-nickel alloys are used extensively in the electrical industry owing to their exceptional magnetic properties. Alloys containing 20 to 30 Ni are non-magnetic and are used to some extent for non-magnetic parts in electrical machinery. Alloys having a high permeability and low hysteresis loss have a composition between 45 and 80 Ni, two of the better known being **Permalloy** with 78.5 Ni and **Hipernik** with 50 Ni. **Perminvar** (45 Ni, 25 Co) has a constant permeability over a range of flux densities. The magnetic properties of various alloys are given in Table 22.

Table 22. Magnetic Properties of Various Alloys
(A.S.M. Metals Handbook, 1939)

Material*	Initial permeability	Maximum permeability	Hysteresis loss, ergs per cc per cycle[a]	Residual induction, gausses	Coercive force, oersteds[a]	Saturation value, gausses[b]	Resistivity, microhm cm

7–45–25 Mo-Perminvar, baked	550	3,700	2,600	4,300	0.65	10,300	80
70–7.5 Perminvar, annealed	750	3,500	.....	.....	0.8	12,000	16

* Single numbers preceding the word "Permalloy" signify the nickel content, and double numbers signify first the content of chromium or molybdenum, and second the nickel content, the balance being iron in each case. The two large numbers before "Perminvar" indicate the nickel and cobalt contents, respectively, and the small initial number indicates the molybdenum content.

[a] For saturation value of the flux density.

[b] Saturation value of the intrinsic induction.

Another important group of nickel-iron base alloys are those with low coefficients of expansion. **Invar**, containing 36 Ni, has an exceedingly low coefficient of linear expansion. Within limits of atmospheric temperature change, its expansion is proportional to the temperature and it is therefore used for secondary standards of length. **Elinvar** (32 Ni with small percentages of Cr, W, Mn, Si, and C) not only has a low coefficient of expansion but also has a constant modulus of elasticity over the temperature range of 0 to 100 F and is thus useful in hairsprings for watches and springs for other precision instruments. **Platinite**, a 46 Ni alloy, has the same thermal coefficient of expansion as platinum; and **Dumet wire**, a 42 Ni alloy covered with copper to prevent gassing at the seal, is used to replace platinum as the "seal-in" wire in incandescent lamps and vacuum tubes.

Electrical sheet steels are alloys of iron and silicon with C, Mn, P, and S *kept as low as possible. The silicon increases the electrical resistivity of iron* and greatly decreases the hysteresis loss; silicon-alloy sheets are used in almost all magnetic circuits where alternating current is used. For transformers, the silicon content is around 5 percent, but in structures subjected

Stainless Steels

Corrosion and Heat-resisting Steels. Certain alloys of iron and chromium are highly resistant to corrosion and oxidation at high temperatures and maintain considerable strength at these temperatures. These alloys sometimes contain nickel and small percentages of silicon, molybdenum, tungsten, or copper. This large and complex group of alloys is known as **stainless steels,** although none of them are truly stainless and many are not steels in the sense that they do not harden on quenching. See Thum, "The Book of Stainless Steels" (A.S.M., 1935) for details of the production, fabrication, and properties of these alloys.

Stainless steels may be classified according to their microstructure as follows: (A) **hardenable alloys** containing up to 16 percent chromium and 0.70 percent carbon which are martensitic when quenched; (B) **low-carbon, non-hardenable alloys** which are ferritic and contain more than 16 percent chromium; and (C) **chromium-nickel alloys** which are austenitic. Some of the properties of these three different groups of stainless steels are as follows.

Chemical Analysis. Group A. (Martensitic.) Chromium less than about 16 percent; carbon less than about 0.40 percent. May contain small percentages of tungsten, copper, nickel, silicon, molybdenum. Group is magnetic.

B. (Ferritic.) Chromium more than about 16 percent; carbon quite low, but can increase as chromium goes up. May contain small percentages of copper, nickel, silicon, molybdenum, tungsten. This group is magnetic.

C. (Austenitic.) Contain enough chromium and nickel to make steel austenitic and non-magnetic. Usually contain twice as much chromium as nickel or vice versa; total alloy content at least 26 percent. Carbon quite low.

Heat-treatment. A. Respond to hardening, tempering, and drawing. Resulting physical properties depend on chemical analysis (principally carbon content).

B. 18 percent chromium toughened by long anneal at more than 1400 F, and air cooling. Avoid decarburizing the skin. 25 percent chromium gets best strength and toughness by rapid cooling from 1650 F.

C. Do not respond to hardening by heat-treatment. Must be rapidly cooled from 1800 to 2150 F to have austenitic structure (Brinell 140 to 170).

Toughness. A. Are structurally dependable. After tempering are not brittle in notched sections or under impact.

B. Laminated structure, from coarse ferrite in ingot, causes low impact values, but proper rolling and heating gives adequate toughness in rods, bars, and sheets.

C. Extremely tough at all times, including liquid air temperatures. Dependable against shock except when corroded at grain boundaries (a preventable condition).

Grain Growth and Structural Changes at High Temperatures. A. Not subject to excessive grain growth. Thoroughly dependable for supporting any load or shock within their carrying capacity up to 1400 F.

B. The pure chromium irons low in carbon and those containing high silicon or aluminum (when cold worked) are subject to excessive grain growth, especially above 1900 F. Grain growth is reduced by carbon, manganese, copper, nickel, titanium, and vanadium. Some alloys containing them are not subject to grain growth.

Long service at 800 to 950 F makes them brittle when cold, although they are not brittle at working temperatures.

C. Tend to precipitate carbides at grain boundaries during service at 800 to 1500 F, losing some toughness and becoming susceptible to intergranular attack by strong corrodents. This is controlled by very low carbon, by titanium or columbium, or by prior "stabilization."

Strength at Elevated Temperatures. A. Much better than straight carbon steel for temperatures up to 1000 or 1200 F. Retain tensile properties up to 750 F.

B. Heat-resisting varieties quite tough at temperatures up to 1600 F. Superior in ductility to Group C but not in creep resistance.

WIRE, SHEETS, AND BARS

Wire and Sheet Metal Gages. Wire and sheet metal of the smaller thicknesses are made to various gages. Steel wire is usually made to the Washburn and Moen (W & M) or Roebling gage. The U. S. standard for sheet metal is based upon weight per square foot; the tabulated values are the corresponding thicknesses for wrought iron weighing 480, and for steel and open-hearth iron weighing 489.6 lb per cu ft. Stubs steel wire gage is also used for numbered twist drill sizes. The Birmingham wire gage is used in the U. S. for brass wire. The Brown and Sharpe gage is a uniform geometrical progression, each gage being equal to 0.89053 times the preceding gage. See p. 1690 for more data on the Brown and Sharpe gage.

to vibration, such as motor armatures, the silicon is usually kept below 4 percent because of the brittleness of high silicon sheets.

Austenitic manganese steel (Hadfield's manganese steel) is a nonmagnetic alloy containing around 12 Mn and 1 C. It is relatively soft but work hardens on the surface when subjected to severe abrasion, so that it is extremely useful in crushing machinery, for railroad crossings and frogs, tractor shoes, etc. As cast, this alloy is partly martensitic and therefore hard and brittle. By quenching from a high temperature (1900 F), a homogeneous austenite is retained and the alloy has the high toughness, strength, and ductility characteristic of austenitic steels.

A.S.T.M. Specifications

The A.S.T.M. Standards, Part I, 1939, contain over two hundred specifications for ferrous materials and products. For detailed specifications and for chemical analyses reference should be made to these Standards. The specifications contain also details of the preparation of test specimens, the location from which they should be taken, and permissible variations in the dimensions of material ordered.

The physical properties specified for some of the more common ferrous products are contained in Tables 23 and 24. The products designated by the specification number in the first column of Table 23 are as follows:

STEEL FOR BRIDGES AND BUILDINGS

- A7–39 Plates, Sections, Bars, and Eyebar Flats
- A10–39 Mild Steel Plates
- A78–39 Plates for Forge Welding
- A141–39 Structural Rivet Steel
- A8–39 Structural Nickel Steel
- A94–39 Structural Silicon Steel
- A131–39 Structural Steel for Ships

STEEL FOR BOILERS

- A70–39 Carbon Steel Plates
- A201–39 Carbon-silicon Steel Plates
- A212–39 High Tensile Stress Carbon-silicon Steel Plates
- A31–39 Boiler Rivet Steels
- A53–36 Steel Pipe
- A106–39 Steel Pipe for High Temperatures
- A187–38 Seamless Cold-drawn Alloy Heat Exchanger Tubes

RAILROAD STEELS

- A113–39 Structural Steel for Locomotives and Cars
- A26–39 Steel Tires

BILLET-STEEL BARS FOR CONCRETE REINFORCEMENT

- A15–39

Weights of Square and Round Steel Bars

[a] Specimen to bend flat on itself without cracking on outside of the bend.
[b] To bend 90 deg without cracking.

Modifications in Elongation

[49] Elongation in 8 in., min., percent = 1,500,000/T.S. For materials over ¾ in. in thickness or diameter, a deduction from the above elongation of 0.25 percent shall be made for each increase of 1/32 in. of thickness or diameter above ¾ in., to a minimum of 18 percent, except for eyebar flats unannealed, which shall have a minimum of 14 percent.

For material under 5/16 in. in thickness or diameter, a deduction from the above elongation of 1.25 percent shall be made for each decrease of 1/32 in. of the specified thickness or diameter under 5/16 in.

[50] Elongation in 8 in., min, percent = 1,600,000/T.S. for structural nickel steel; 1,500,000/T.S. for structural silicon steel. For material over ¾ in. diam or thickness, a deduction from the above elongation of 0.25 percent shall be made for each increase of 1/16 in. diam or thickness over ¾ in., to a minimum of 14 percent. For material under 5/16 in. diam or thickness, *a deduction from the above elongation of 1.25 percent* shall be made for each decrease of 1/32 in. diam or thickness below 5/16 in.

[51] Elongation in 2 in., min, percent = 1,700,000/T.S.

[52] For material over ¾ in. diam or thickness, a deduction from the percentage reduction in area of 0.50 percent shall be made for each increase of 1/16 in. diam or thickness above ¾ in. (to a minimum of 24 percent in the case of silicon steel).

[53] Elongation in 2 in., min, percent = 1,600,000/T.S.

[54] Elongation in 8 in., min, percent = 1,500,000/T.S. for flange; 1,550,000/T.S., but not less than 25 percent, for firebox.

For material over ¾ in. in thickness a deduction from the above elongation of 0.125 percent shall be made for each increase in thickness of 1/32 in. over ¾ in. to a minimum of 21 percent for flange steel and 22 percent for firebox steel.

[55] Elongation in 2 in., min, percent = 1,700,000/T.S. *For material over 2½ in. in* thickness a deduction from the above elongation of 0.5 percent shall be made for each increase of ½ in. of thickness above 2½ in.

[56] Elongation in 8 in., min, percent = 1,550,000/T.S. for flange; 1,600,000/T.S. *for* firebox. For material over ¾ in. *in* thickness, a deduction from the above elongation

IRON AND STEEL CASTINGS

BY

CHARLES W. BRIGGS

REFERENCES: Bolton, "Gray Cast Iron," Penton. Hall, "The Steel Foundry," McGraw-Hill. Moldenke, "Principles of Iron Founding," McGraw-Hill. Sisco, "Alloys of Iron and Carbon," vol. II, McGraw-Hill. "Metals Handbook," A. S. M. "Cast Metals Handbook," American Foundrymen's Association. "Steel Castings Handbook," Steel Founders' Society.

Classification of Castings

The following classification of the regular ferrous foundry product is customary. See also p. 535.

Gray-iron Castings. The vast majority of gray irons fall within the range of composition: carbon, 2.50 to 3.70 percent and silicon, 0.50 to 3.00 percent. Three types of castings are made in the ordinary gray-iron jobbing foundry.

Soft gray-iron machinery castings are made from an iron that can be machined readily, is not specially strong, and is sound and reliable; they should be used for the ordinary run of machine construction work. Composition varies with the weight of the casting, light, medium, and heavy. Medium machinery mixtures (see Table 1) are used for ordinary castings satisfactorily, but it is not safe to make heavy castings from light machinery mixtures, as they will be very weak; very light castings from heavy machinery mixtures will be quite hard.

Strong gray-iron machinery castings are adapted for medium and heavy work where a greater strength than that of ordinary cast iron is desired, but not the special strength of the steel casting. They are made by adding 10 to 40 percent of steel scrap to the ordinary mixtures in which the required silicon has been provided to carry the steel burden safely. There is much variation in the strength of such castings; where extreme care must be exercised, it is safer to use steel castings.

Chilled-iron Castings. Such castings as crusher jaws, grinding plates, etc., requiring chilled-iron surfaces and soft bodies, are made in the jobbing foundry from special low-silicon irons. Chilled rolls, car wheels (chilled treads), and work of a similar nature are better obtained from roll or car-wheel foundries, as these work to service guarantees and are specially careful in the selection of their melting stock.

Special Gray-iron Castings. Special attention must be given to certain speciality castings. Thus, ornamental castings are made from high-phosphorous high-silicon iron, which is very fluid when molten, in order to fill the finest lines in the mold. See Table 1 for such special castings.

Malleable castings range in strength between gray iron and the steel castings; they are used where gray iron is too weak and steel too expensive. They are made ordinarily in sections less than ¾ in. thick, the pieces not much over 4 ft in length, and the weight not over 300 lb. The usual weights are a few ounces for light, 15 lb for medium, and 150 lb for heavy castings. The metal will bend, twist, and resist shock remarkably well—its special characteristic—better even than cast steel, is cheap, easily made, and specially adapted to repetition work, and therefore in general use for car castings, pipe fittings, agricultural work, hardware, etc. The minimum tensile strength should be 50,000 lb with the yield point at 30,000 lb per sq in. min and at least 10 percent elongation in 2 in.

USES OF STEELS LISTED

Class A, for forgings which may be welded or case-hardened.

Class B, for mild-steel forgings for structural purposes, for minor ship fittings, etc.

Class C, for mild-steel forgings for structural purposes, for ships, etc.

Classes D, E, F, G, H, and I, for various machinery forgings, choice depending upon design and upon the stresses and services to be imposed.

Classes K, L, and M, for various machinery forgings, choice depending upon design and upon the stresses and services to be imposed, and upon the character of machining operations to be done.

PERCENTAGE CHEMICAL COMPOSITION

Class A: Mn, 0.30–0.60, P, ≦0.05, both acid and basic; S, ≦0.05.

Classes B, C, D, E, F, and G: Mn, 0.40–0.80; P, ≦0.05, both acid and basic; S, ≦0.05.

Classes H and I: Mn, 0.40–0.80; P, ≦0.04, both acid and basic; S, ≦0.05; Ni, ≦3.00.

Classes K and L: P, ≦0.05 (acid), or ≦0.04 (basic); S, ≦0.05.

Class M: P, ≦0.04 (acid or basic); S, ≦0.05. The composition of alloy steel, other than P and S, to be agreed upon between manufacturer and purchaser.

SIZES

(a) Not over 8 in. in outside diameter or overall thickness.

(b) Over 8 to 12 in., inclusive.
(c) Over 12 to 20 in., inclusive.
(d) Up to 4 in., 2-in. max wall.
(e) Over 4 to 7 in., 3½-in. max wall.
(f) Over 7 to 10 in., 5-in. max wall.
(g) Over 10 to 20 in., 5- to 8-in. max wall.
(h) Up to 2 in., 1-in. max wall.

Specifications for Classes A, B, C, D, E, F, H are for forgings whose max outside diameter or overall thickness is not over 20 in. Specifications for Classes G, I, are for forgings whose max outside diameter or thickness is not over 10 in. when solid, and not over 20 in. when bored.

Steel castings are divided into two main classes, carbon and alloy. Each class is subdivided according to composition.

Carbon cast-steels are divided into two classes: (1) medium-carbon cast steels, containing 0.20 to 0.40 C, and (2) special-carbon cast steels containing (*a*) less than 0.20 C and (*b*) more than 0.40 C.

Alloy cast steels are divided into two classes: (1) low-alloy cast steels containing special alloying elements totaling less than 8 percent, and (2) high-alloy cast steels containing 8 percent or more special alloying elements. This class includes the heat- and corrosion-resistant steels and austenitic manganese steel.

The steel casting should be selected where strength, ductility, and reliability are essential.

CAST IRON

Effect of Element Additions. Cast iron includes a whole series of alloys of iron, carbon, and silicon, all of which contain free graphite flakes in the as-cast condition. Besides carbon, iron, and silicon, commercial cast-iron contains appreciable percentages of phosphorus, sulphur, and manganese.

Carbon. Beginning with the smallest percentages of carbon, there are the three commercial grades of steel castings. Just beyond a 2 percent content will be found the hard castings making tough (when good) malleables. Also, some of the special high-strength irons may have carbon contents well under 2.50 percent. From 2.50 percent on, good malleables are obtained, and from 2.75 percent upward the strong cast-iron varieties. The upper limit for ordinary cast irons is 3.75 percent. Low-silicon charcoal irons used for chilled-casting work run up to 4.25 percent.

The carbon in iron is of two general kinds: (1) **combined carbon** as carbides of iron; (2) **graphite**, or uncombined carbon, present as a mechanical admixture. The latter form of carbon is subdivided into two classes: (*a*) The crystalline graphite present in gray iron, produced in the "setting" of the molten metal and varying in size from the big-flaked "kish" thrown off as excess carbon from blast-furnace casts to the very finely crystallized graphite of the soft cast irons made to set very quickly by means of chills; (*b*) graphite found in malleable castings and resulting from the heat-treatment of white irons of the proper composition. Instead of separating out in the molten mass while setting, this graphite is formed from the solid, the amorphous particles reposing in the interstices of the crystalline iron structure which are opened up by the long-continued high-temperature application. It is amorphous in shape and is called **temper carbon.**

In cast-iron founding, where subsequent heat-treatment is used only for removing casting strains, as in softening iron pipe centrifugally-cast in metal molds, the total carbon present may be either all in the combined state, as one extreme, making white-fracture hard brittle and almost useless castings, or all graphitic, as the other extreme, making a black-fracture soft easily-machined and highly useful iron. This range is due largely to the percentage of the other elements present (notably the silicon), the degree of superheat attained in melting, the rate of cooling in the mold after pouring (a function of the thickness of section), and, in some degree, the pouring temperature.

Silicon has a powerful softening effect; its presence in cast iron reduces the ability of the iron to retain carbon in chemical combination. With silicon almost entirely absent, the iron will retain all its carbon in combination, making white iron. With about 3 percent silicon present, almost no carbon can be held in chemical combination, and gray iron results. Beyond 3

Wire and Sheet Metal Gages

(Diameters and thicknesses in decimal parts of an inch.)

Gage No.	American wire gage, or Brown & Sharpe (for non-ferrous sheet and wire)	Steel wire gage or Washburn & Moen or Roebling (for steel wire)	Birmingham wire gage (B.W.G.) or Stubs iron wire (for steel rods or sheets)	Stubs steel wire gage	British Imperial standard wire gage (S.W.G.) effect in carbide stabilization, the use of chromium in gray irons is restricted to percentages usually below 1 percent. High-chromium cast irons (20 to 35 percent chromium) show good corrosion and heat resistance and resistance to erosive wear.

Other Elements. Molybdenum, titanium, vanadium, aluminum, copper, etc., are seldom found in pig iron in sufficient quantity to be considered; they are, however, added to cast iron in small quantities in order to produce special effects.

Physical Characteristics

Shrinkage and Contraction. The term shrinkage is usually employed where contraction is really meant. Contraction in a casting is the reduction in dimensions due to the cooling from the temperature at the moment of solidification to the ordinary temperature of the atmosphere. Shrinkage, or liquid contraction, on the other hand, is the separation of the portions of metal from each other, due to an insufficient supply of liquid metal to fill up the spaces left by the reduction in volume as the iron solidifies. This forms spongy spots and actual cavities, the walls of which may be lined with pine-tree crystals of iron. Shrinkages greatly weaken the interior structure of the metal and are highly dangerous through their concealed position.

Irons that throw out graphite on solidifying will not contract nearly so much as those in which this does not occur. The ordinary contraction of gray iron is ⅛ in. per ft. That of white iron and steel is about ¼ in., but varies with differences in the rate of cooling, the composition of the metal, and the shape of the pattern. In the case of malleable castings, where the original hard-iron casting should contract ¼ in. (one-half of which is restored in the annealing process), some parts do not contract at all, although others show a contraction of $\frac{5}{16}$ in. per ft. This indicates that some portions are held tight in the mold and are actually stretched in the setting, and others readily pull away from the walls of the mold.

The most frequent **segregations** consist of hard spots of manganese and sulphur-iron compounds, which interfere with machining where the two elements are too high, and of iron phosphide, accompanied by increased hardness in the center of a heavy section made with too-high-phosphorus iron. There may be an artificial chilling of the metal in spots, through improper cooling, with consequent hardening effects.

Aging of Iron Castings. In order to reduce or, if possible, remove casting strains, it has been the custom, where permanent accuracy in finishing castings is desired, to store the rough casting for about 6 months before using them. In present-day production this is seldom possible, and the same object can be attained by a short heat-treatment. The castings, after cleaning, are brought to a temperature of between 500 and 600 F and left over night. Another way is to anneal at 1250 F for about 4 hr after the interior is fully heated and then cool gradually. The best result is obtained by annealing at the high temperature after the first cut has been taken. The metal will then be free from casting strains when the finishing cut is given.

Heat-treatment. Heat-treatments applied to cast irons are relatively new developments. They offer opportunities for improvements in quality and certain economies. Different treatments are used for different purposes. These may be summarized as follows:

1. Quick aging to remove internal stresses. Usual temperature 900 F.
2. Quenching and drawing to increase hardness and strength. Usual oil quench from 1500 to 1550 F followed by a draw to 700 F or above.

Weights of Flat Rolled Steel, Pounds per Linear Foot*

(The last line of the table gives weights per square feet)

* For other widths the weights are obtainable by addition; for example, $54 \times \frac{3}{4}$ in. $= [(10 \times 5) + 4] \times \frac{3}{4}$ in., and weight $= (10 \times 12.75) + 10.20 = 137.7$ lb. Similarly, for greater thicknesses, the weights are obtainable by addition.

melting charges to cut down the total carbon, and at the same time superheat to higher temperature ranges, the **tensile strength** is raised, so that, in rather small sections, it is not uncommon to get a value of 45,000 lb per sq in. High-test cast iron can now be made by advanced foundrymen up to 55,000 lb and, with nickel added, even higher. These high values are, however, not yet readily obtainable. Where special strength is wanted, an iron not under 30,000 lb per sq in tensile strength should be specified. The tensile test for cast iron is not to be recommended unless the greatest care is taken with the preparation and testing of the specimen. American specifications make the tensile test optional and at the expense of the purchaser.

The **transverse strength** of cast iron is the one most readily obtainable for specification purposes. The test bar of the A.S.T.M. is 1.20 in. diam, 21 in. long, and is broken transversely on supports 18 in. apart. A breaking strength of about 2,200 lb for the test bar, with a deflection of 0.25 in. or over, indicates a good iron for ordinary use.

The **elastic limit** of cast iron is close to its ultimate breaking strength. The **crushing strength** of cast iron is probably its most important characteristic, and gives it its value for structural use. It runs from 80,000 to 140,000 lb per sq in. The resistance to shock of cast iron is not high. On the other hand, the malleable casting has this as its prime characteristic. Hardness in ordinary cast irons is a condition that may be brought about artificially, if desired, by chilling the molten metal in the molds. Only the lower silicon irons are amenable. The mechanical properties of cast irons are given in

Other specifications for cast iron are as follows:

Automotive Gray-iron Castings, Spec. A159-40, A.S.T.M. Standards, 1940, Part 1, p. 143. "Gray-iron Castings for Valves, Flanges and Pipe Fittings," A126-40, A.S.T.M. Standards, 1940, Part 1, p. 140. "Lightweight and Thin-sectioned Gray-iron Castings," Specification A190-40, A.S.T.M. Standards, 1940, Part 1, p. 138. "Locomotive Cylinders, Cast Iron," A45-14, A.S.T.M. Standards, 1939, Part 1, p. 491.

Foundry Practice

Materials. **Pig irons** may be divided into: charcoal irons, coke irons, and electrically made pig irons. **Charcoal iron** was formerly used much for malleable castings, car wheels, and other work requiring chilling in whole or in part. Today it is used only for chilled rolls, crusher jaws, and castings that require chilled parts and great strength. Electrically made pig iron is now being made in Norway and imported into America. It is of very high quality and expensive. The bulk of foundry pig iron is made with coke as the fuel. Pig iron is now bought entirely on its composition.

The requirements of the foundry trade being sharply defined by the classes of castings made, the product of the blast furnace readily divides itself on the phosphorus content. Thus, high-phosphorus pig irons go to the stove trade, and very low-phosphorus irons, everything else being acceptable, go to the steel foundry. In a lesser degree, the sulphur plays a part, the very high-sulphur irons being unsuitable for the better grades of castings. High sulphur means a low selling price. Manganese is kept between 0.60 and 1.00 as a general rule. The silicon content is the determining factor in the purchase. The foundryman specifies the silicon and usually also the maximum sulphur.

In order that there may be uniformity in quotations, the following percentages and variations are used. The permissible variations are from the A.S.T.M. specification A43-24. These specifications do not advise that all five elements be specified in all contracts for pig iron, but do recommend that when these elements are specified the following percentages be used:

Recommended Chemical Specifications of Pig Iron

Silicon (0.25 allowed either way)	Sulphur (maximum)	Total carbon (minimum)	Manganese (0.20 either way)	Phosphorus (0.15 either way)
1.00	0.04	3.00	0.20	0.20
1.50	0.05	3.20	0.40	0.40
2.00	0.06	3.40	0.60	0.60
2.50	0.07	3.60	0.80	0.80
3.00	0.08	3.80	1.00	1.00
	0.09		1.25	1.25
	0.10		1.50	1.50

Percentages of any element may be specified one-half way between the above. In case of phosphorus and manganese, the percentages may be used as maximum or minimum figures, but unless so specified they are considered to include the variations above given.

Scrap is of two kinds, **domestic**, or that made in the foundry itself and which remains and is used in the daily heats; and **foreign**, or scrap which is bought in the open market and consists of several grades of heavy and light scrap machinery, pipe, stove plate, etc. Purchased scrap must be watched closely for undesirable elements.

Steel when used in foundry practice should be neither light nor heavy in section. Clippings from structural steel, rail ends, boiler plate, etc., are best. Steel should be charged directly on the fuel, pig iron over it, and then scrap cast iron. In this way, all portions of the mixture melt at about the same time and good mixing results.

percent, silicon begins to act as a hardener; the Scotch or silvery irons, the high-percentage-silicon pig irons, and finally the ferrosilicons up to metallic silicon are brittle substances.

In gray-iron work, the proper selection of the silicon content in the mixture is the most important factor. Within given limits of the other elements, every change desired can be brought out in the castings, so far as their strength, machining qualities, etc., are concerned, by variation in the silicon.

In malleable-casting work the silicon is even more important, as the range is quite small for a casting of given section.

Acidproof cast iron is now made in large quantities for the chemical industry. It is an ordinary cast iron with the silicon content raised to 14 percent, is white in fracture and very brittle. All surfaces are curved and fairly thick to reduce the casting strains. Castings of this description have trade names, such as **Duriron** and **Tantiron.**

Sulphur is an objectionable impurity in iron castings of practically all kinds, the iron-sulphur compounds being both brittle and weak. Sulphur ranges from about 0.08 to 0.15 percent in the majority of commercial irons, probably averaging about 0.10 percent. Its only redeeming feature is that high-sulphur castings cut freely under the tool, giving clean threads and surfaces.

Sulphur hardens iron by counteracting silicon in its power to form graphite. Hence, where high sulphur is present, proportionally more silicon must be charged.

Manganese promotes the retention of carbon in the combined form and hence counteracts silicon. This effect is not specially noticeable until the percentage of Mn passes 1.00. Manganese content usually ranges from 0.50 to 0.80 percent, although irons slightly above or below that range are not uncommon. In the case of malleable castings, the effect of over 0.40 Mn is noticeable in the annealing process, where it retards the opening up of the structure of the metal to allow the separating out of the "temper carbon" and for that reason is injurious. When sulphur is high, manganese will combine with it, and if, after tapping, with extremely hot iron, the metal is allowed to stand for a while, manganese sulphide rises and can be skimmed off with what slag has come up also, thus often reducing the sulphur of the metal by one-half.

Phosphorus. The great value of phosphorus is to make iron very fluid when molten. Hence its use for art work, stoves, radiators, and similar thin and not necessarily strong castings. Phosphorus is a hardener and requires the presence of the proper amount of silicon. The castings made with phosphorus irons being thin, there must be enough silicon present to prevent the retention of combined carbon, as thin sections cool at a rapid rate in the sand after casting. Up to 0.25 percent is considered low phosphorus, 0.30 to 0.70 percent medium, and above this to 1.50 percent is high.

Nickel is becoming an important factor in high-quality cast iron. As cast iron may be considered as essentially a matrix of indifferent steel, cut up and weakened by mechanically mixed graphite, anything to improve the matrix will be of value. Nickel up to 2 percent is best adapted for this purpose. While increasing the strength, it keeps the iron readily machinable by promoting the graphite formation. Higher percentages of nickel, from 4 to 20 percent, are used for castings of a specialized nature.

Chromium is employed in cast irons for two major purposes, *viz.*, to stabilize the carbides and increase corrosion resistance. Owing to its marked

A cupola 30 in. diam inside the lining is about as small as should be used in commercial practice.

The air furnace is a straight-draft reverberatory furnace. Metal in the hearth is melted by heat absorbed from the flame and hot gases passing over the hearth and by radiation from the roof and sides. Air furnaces regularly used in gray-iron melting usually are of large capacity, 20 tons or more of iron being melted in each batch. Pulverized coal is the common fuel, though oil is also used. The charge should be stacked in such a manner that the hot gases can pass through readily. In melting down, a short hot flame is desired, and the usual practice is to keep excessive slag scraped off. The bath should be well rabbled to mix the metal thoroughly. There is always some oxidation and silicon, manganese, and carbon are lowered. The advantage of the air furnace is that it gives a large amount of high-grade metal at one tap. The absence of direct contact of metal and fuel makes possible the very considerable reduction in total carbon by steel additions, without danger of picking up carbon from the fuel afterward. Heavy pieces of scrap, which could not go into a cupola, may be used.

The electric furnace is generally used for producing high-strength irons and highly superheated irons for light work. Metal composition is altered but little during the melting processes, and oxidation loss is avoided. The electric furnace is well adapted to melting special high-alloy cast irons.

An economical application of the electric furnace in the iron foundry is in connection with the cupola melting process. Molten metal from the cupola is transferred to the electric furnace and given 20 to 30 min treatment. The sulphur can readily be cut down to 0.04 in this time (in a basic lined furnace) and a high degree of superheat and deoxidation achieved.

MALLEABLE IRON CASTINGS

Malleable iron castings as manufactured in this country are used in large quantities in the construction of automobiles, at least half of the yearly production being used for this purpose. The agricultural-implement industry and the railroads are large users, and miscellaneous castings for diversified use account for the balance of the output. They are preferable to cast iron for any use where capacity to withstand impact, occasional overloads, or constant abuse in service is a requisite.

Malleable iron is strong, tough, and ductile; it consists of a matrix of silico-ferrite throughout which are uniformly distributed small nodules of temper carbon. The castings, from the air furnace, the electric, or open-hearth furnace, are hard or white-iron castings; they are made up wholly of pearlite and free cementite.

For the past 10 years, the average ultimate strength, yield point, and elongation in over 60 plants in different parts of the country are, respectively, 54,117 lb, 36,371 lb per sq in., and 18.49 percent in 2 in. The yield point is about 67 percent of the ultimate strength, which is very exceptional in the case of a soft and very ductile metal.

The following average data are taken from the A.S.T.M. and the Am. Foundrymen's Assoc., 1937 Joint Symposium on Malleable Iron Castings: Modulus of elasticity in tension, 25,000,000 lb per sq in.; Brinell hardness, 115; shearing strength, 48,000 lb per sq in.; modulus of rupture in torsion, 58,000 lb per sq in.; specific gravity, 7.40.

The average chemical composition of the hard-iron castings can be taken as: Si, 1.00; P, 0.16; S, 0.085; Mn, 0.280; combined C, 2.45.

3. Production of high-strength semi-malleable by anneal, quench, and draw.
4. Production of an extreme hard case by nitriding after suitable heat-treatment and machining operations.
5. Annealing to soften for increase in machinability. Usual range 1350 to 1500 F.

Many combinations of treatments are possible; only the more typical are mentioned.

Mechanical Properties

Strength of Cast Iron. A cast iron with a tensile strength of 25,000 lb per sq in. is considered a good metal. By the addition of steel scrap in the

Irons I,U,F,O—Miscellaneous soft-iron castings.
Irons D,E,R—Strong gray-iron machinery castings.
Irons Q,V—High-test castings.

Standard Specifications for Malleable Castings

(A.S.T.M. Specification A47-33)

1. These specifications cover malleable castings for railroad, motor-vehicle, agricultural-implement, and general-machinery purposes.

2. The castings shall be produced by either the air-furnace, open-hearth, or electric-furnace process.

3. The tension-test specimens specified shall conform to the following minimum requirements as to tensile properties:

	Grade 32510	Grade 35018
Tensile strength, psi	50,000	53,000
Yield point, psi	32,500	35,000
Elongation in 2 in., percent	10.0	18.0

4. *a.* All castings, if of sufficient size, shall have cast thereon test lugs of a size proportional to the thickness of the casting, but not exceeding 5/8 by 3/4 in. in cross section. On castings which are 24 in. or over in length, a test lug shall be cast near each end. These test lugs shall be attached to the casting at such a point that they will not interfere with the assembling of the castings, and may be broken off by the inspector.

b. If the purchaser or his representative so desires, a casting may be tested to destruction. Such a casting shall show good tough malleable iron.

5. *a.* Tension test specimens shall be of the form and dimensions shown in Fig. 1. Specimens whose mean diameter at the smallest section is less than 19/32 in. will not be accepted for test.

b. A set of three tension test specimens shall be cast from each melt, without chills, using heavy risers of sufficient height to secure sound bars. The specimens shall be suitably marked for identification with the melt. Each set of specimens so cast shall be placed in some one oven containing castings to be annealed.

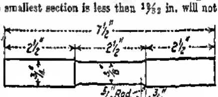

FIG. 1.—Tension Test Specimen for Malleable Iron.

6. *a.* After annealing, three tension test specimens shall be selected by the inspector as representing the castings in the oven from which these specimens are taken.

b. If the first specimen conforms to the specified requirements, or if, in the event of failure of the first specimen, the second and third specimens conform to the requirements, the castings in that oven shall be accepted, except that any casting may be rejected if its test lug shows that it has not been properly annealed. If either the second or third specimen fails to conform to the requirements, the entire contents of that oven shall be rejected.

7. Any castings rejected for insufficient annealing may be reannealed once. The reannealed castings shall be inspected, and if the remaining test lugs, or castings broken as specimens, show the castings to be thoroughly annealed, they shall be accepted; if not, they shall be finally rejected.

8. The castings shall conform substantially to the patterns or drawings furnished by the purchaser and also to gages which may be specified in individual cases. The castings shall be made in a workmanlike manner. A variation of 1/8 in. per ft will be permitted.

9. The castings shall be free from injurious defects.

STEEL CASTINGS

Effect of Element Additions. The elements always contained in steel and usually determined by analysis are carbon, manganese, silicon, phosphorus, and sulphur. Alloy additions consist of nickel, chromium, molybdenum, vanadium, copper, titanium, and aluminum.

Carbon. In general, tensile strength and yield point increase and ductility decreases with increasing carbon content.

Tables 2 and 3. The properties and composition of special alloy cast irons used for wear, heat, and oxygen resistance are given in Table 4.

Table 4. Special Alloy Cast Irons

Commercial name or type	Average composition, percent						Mechanical properties		Resistant to

Specifications for Castings

Standard Specifications for Gray-iron Castings

(Summary of A.S.T.M. Specifications A48-36)

1. These specifications apply to gray-iron castings where strength is a consideration. It is a purpose of these specifications to classify cast irons in respect to tensile strength.

2. Tensile Strength Classification. Gray-iron castings conforming to these specifications shall be known and listed by classes according to minimum tensile strengths of test bars, as follows:

Class	20	25	30	35	40	50	60
Min tensile strength, psi	20,000	25,000	30,000	35,000	40,000	50,000	60,000

3. Transverse tests shall be optional, and the following minimum breaking loads are specified:

Class		20	25	30	35	40	50	60
Min breaking load at center, lb	A	900	1,025	1,150	1,275	1,400	1,675	1,925
	B	1,800	2,000	2,200	2,400	2,600	3,000	3,400
	C	6,000	6,800	7,600	8,300	9,100	10,300	

4. The transverse breaking loads are based on actual averages of transverse test loads for each casting. It is not implied by these specifications that the ratio of tensile strength to transverse load is constant.

5. When an iron is specified by class and the transverse test bar fails to meet the load requirements, then the manufacturer shall have the right to have tested a tension-test specimen machined from a broken end of the transverse bar. In the event that this tension specimen meets the requirements of the specified class, the class requirement shall be considered as having been met, irrespective of the transverse breaking load.

6. Test bars shall be cast separately from the casting. Three standard sizes of transverse test bars are available under the specifications.

Transverse test bar A is 0.875 in. diam, 15 in. long, and 12 in. between supports. Transverse test bar B is 1.20 in. diam, 21 in. long, and 18 in. between supports. Transverse test bar C is 2.00 in. diam, 27 in. long, and 24 in. between supports.

7. The test bars shall be made under the same sand conditions as the castings and shall receive the same mechanical and thermal treatment as the castings.

to hinder contraction. Pattern makers in general use a "pattern-maker's" shrinkage of ¼ in. per ft for open construction and $\frac{3}{16}$ to ⅛ in. for hindered contraction. The solidifying contraction must be controlled by the use of risers or sink heads which are reservoirs of metal placed at points of final solidification within the casting in order to prevent shrinkage cavities and internal hot tears. Mold relieving methods must be provided for in order to prevent the external hot tears and cracking of members resulting from high stresses due to hindered contraction.

Steel castings are usually heat-treated to relieve casting strains and to produce a grain structure that gives higher ductility and impact resistance than that found in the as-cast material.

Heat-treatment. Many desired varieties of structure in cast steel of any grade may be developed by heat-treatment. In general, the normal run of carbon cast-steels receives the single normalizing or single annealing heat-treatment. To obtain the correct structural condition throughout the

Table 5. Approximate Chemical Analyses and Quenching and Tempering Temperatures for Alloy Castings

Steels 1–3 are vanadium; 4–6 chromium; 7–9 chrome-vanadium; 10–12 chrome-nickel; 13–15 chrome-molybdenum; 16–19 manganese.

[1] 0.20 to 0.30 Si preferred.
[2] Shock resistance is sometimes improved by oil-quenching from the tempering temperature.
[3] A long soak is required at the tempering temperature.
[4] Water-quenched.
[5] Oil quenched.
[6] Either water- or oil-quenched.

Softeners are the higher silicon pig irons that are added to the mixture to increase the general silicon content. These irons run from 4 to 8 percent silicon and should be used with caution. It is far better to charge pig irons of nearly the right silicon than to use extremes.

Fluxes. As the pig iron and scrap charged into the cupola carry with them sand and rust, and as the ash of the fuel collects in the melting zone, it is essential for long heats that a flux be added to collect this material into a slag that can be drained off. Usually, slagging off a cupola is not resorted to for heats shorter than an hour. Limestone is the universal flux and should contain the maximum possible amount of carbonate of lime. Fluor spar is a flux that thins the slag very much. It should be used sparingly and in connection with limestone on account of its expense and powerful action on the cupola lining. The weight of the flux used is about 2 percent of the weight of the metal.

Melting Processes

The melting may be done in crucibles, in the cupola, in the air furnace, or the electric furnace.

The crucible process is used occasionally in making small amounts of cast iron. The absence of contact between metal and fuel makes this an ideal process, but the output is small and the fuel cost is high.

The cupola is the oldest unit for melting pig irons and scrap and today remains the most widely used. Initial investment is comparatively low, and upkeep expense is reasonable. Operating costs for fuel, refractories, labor, and power are less than for other iron-melting mediums. Anything from all pig iron to all steel charges can be melted. Melting is rapid and continuous. With careful supervision, temperatures of 2750 to 2850 F can be maintained consistently.

Uniformity of composition and physical properties can be held within fairly close limits. Once the metal is melted, readjustments in composition cannot be made. In this respect, the cupola is inferior to the other type of melting units, in which the carbon content can be adjusted subsequent to melting down. Cupola melting of uniform- and high-quality metal requires more knowledge and skill than are demanded by most other iron-melting processes.

The cupola is a shaft furnace, into which a fuel bed is introduced and upon which alternate layers of metal and fuel are charged. Air for combustion is supplied through tuyères near the bottom, placed just high enough to allow the space below to serve as a storage for the required quantity of molten iron. The cupola should be charged in even layers. The bed of fuel is first, with the pig iron spread uniformly upon this, and the scrap iron above. If steel is used, it is spread directly upon the coke below the pig iron. Melting should start about 6 min after air is allowed to enter through the tuyères. The bed of coke is previously heated.

It takes roughly 30,000 cu ft of air to melt 1 ton of iron, and the melting rate depends upon the rate of air supply. Definite sizes of cupolas are best adapted for given melting rates per hour. It is not wise to exceed greatly the rates of melting indicated below, or the quality of the metal produced will suffer.

The heat treatments of alloy castings consist of normalizing, annealing, quenching, and tempering. The last two develop the maximum properties; intermediate properties may be secured by normalizing and tempering only. Full annealing produces only a slight increase in the physical properties not justified by the extra cost of the alloys, and in general should be employed only to increase the machinability of the steel, or for other special purposes.

The range of **mechanical properties** of cast steel is indicated in Tables 6 and 7.

Mechanical properties are determined on a standard 0.505 in. diam test specimen. *Specimens are machined from test coupons about 1 in. thick and* $1\frac{1}{4}$ in. deep, usually attached to the casting. The influence of the mass of a casting on its mechanical properties is shown in Fig. 2.

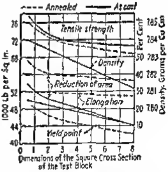

Fig. 2.—Influence of Size on the Mechanical Properties of the Center of a Block of Carbon Cast Steel (C, 0.26; Mn, 0.63; Si, 0.23).

Steel Foundry Practice

The processes used for melting steel for castings are the same as for ingots. The bulk of the tonnage of steel castings is produced *in the acid open-hearth furnace; next* comes the acid electric furnace. The basic electric furnace and the basic open-hearth are used when it is desirable to eliminate both phosphorus and sulphur from the metal during steelmaking. High-frequency induction furnaces are finding use in the production of high-alloy castings, especially those of low carbon content.

By **oxidation of the charge** during melting the carbon, silicon, and manganese are reduced. The carbon elimination is closely watched and is

After heat-treatment, the percentage of the various elements in castings of the foregoing composition will be practically the same, except in respect to the total carbon content, which instead of being in the combined form will be present not only in the form of temper carbon but considerably less in amount than was present in the hard-iron casting. In a ⅝ in thick section, the average loss will be around 0.55 points. Inasmuch as the matrix of malleable iron consists of silicoferrite, a phosphorus content even higher than 0.16 does not affect its toughness and ductility adversely, and if the manganese and sulphur are properly balanced, a sulphur content as high as 0.12 percent is not objectionable.

Annealing or Malleableizing. In the annealing of the original hard castings to produce the malleable-type structure, the castings are placed in metal boxes, usually surrounded with a packing material, supporting the castings in a manner that will prevent warpage. When a muffle furnace is used, the castings are annealed without being packed into boxes. The castings should be raised fairly rapidly to the annealing temperature, which ranges from 1560 to 1600 F. This temperature is maintained for about 60 hr. The temperature then is lowered at a rate of not more than 10 deg per hr until it reaches 1250 F, at which temperature the oven doors may be opened and the castings allowed to cool at a faster rate.

Owing to the high percentage of silicon and carbon, there is scant danger of oxides being present in the molten metal during melting or at the time the furnace is tapped, for which reason no ferroalloys or deoxidizing agents need be added to the bath. For this same reason, coupled with the fact that a relatively low pouring temperature is used, malleable iron is comparatively free from the presence of **non-metallic inclusions** and **blowholes**. The surfaces of the castings are very smooth, with corners sharp and letters or ornamental designs well defined. The examination of assemblies made up of malleable iron that have been exposed to the weather from 20 to 40 years shows that the **rust-resistant** properties of the castings are excellent.

Owing to the fact that the means used for converting the hard-iron castings into the finished product is by heat-treatment at a temperature not very much higher than the critical range, grain size is relatively small, and as the rate of cooling through and under the range is extremely slow, the castings are free from internal strains.

Although malleable castings are **readily machined**, they **cannot be** satisfactorily **welded**, for at a welding temperature the temper carbon will revert to the combined form with the result that most of the tensile properties will be adversely affected.

Malleable castings are extensively used for such purposes as bridge railings, bridge dams, lamp posts, drainage inlets, jack frames, stadium-seat brackets, curb armors, cable brackets, highway road supports, motor-truck parts, kevels, bitts, stair treads, bolts and nuts, awning parts and connecting rods. The castings may vary in weight from a few ounces to half a ton.

Cupola malleable, as distinguished from the regular product, has reference to the process in which the melting unit is the cupola. In this case, the mixture is melted in the presence of coke, instead of in a hearth out of contact with solid fuel, and consequently it is practically impossible to secure a low carbon content in the hard iron castings. The product is therefore inferior even to the lower grade of the A.S.T.M. specification.

Cupola malleable, however, is largely used in the making of fittings of all kinds.

The test coupons shall be cast separately or attached to one or more castings, of the kind ordered by the purchaser, in each melt used for manufacture of the purchased material.

Steel used for the castings shall conform to the following minimum requirements as to tensile properties:

Grade		Tensile strength, min psi	Yield point, min psi	Elongation in 2 in., min percent	Reduction of area, min percent
A-1	Unannealed	60,000	30,000	22	30
A-2	Normalized	60,000	30,000	26	38
A-3	Full annealed	60,000	30,000	24	35
B	Normalized	70,000	38,000	24	36
B-1	Full annealed	66,000	35,000	22	33
B-2	Full annealed	70,000	35,000	20	30
H	Normalized	60,000	43,000	17	25
H-1	Full annealed	80,000	40,000	17	25

7. The castings shall be free from injurious defects.

8. Notes regarding Selection and Characteristics of Grades. Grades A-1, A-2, and A-3 are produced with such low carbon contents as to make the material very soft and easily machinable. These grades are effectively adaptable for fusion fabrication. Grade B (normalized) is used in making a great many carbon-steel castings purchased for miscellaneous industrial application. Grades B-1 and B-2 (full annealed) are for castings which are to be full annealed either to obtain desired properties or to prevent internal stresses. Grade H (normalized) and Grade H-1 (full annealed) are used for

Manganese acts as a deoxidizer on the liquid steel. It also combines with sulphur to form manganese sulphide and prevent "red-shortness." Besides increasing soundness, it increases toughness, tensile strength, and yield point. The normal manganese content of carbon steel castings is 0.50 to 1.00 percent. When cast steel contains over 1.00 percent manganese, it usually is considered to be an alloy cast steel.

Silicon acts as a deoxidizer and promotes soundness in steel. In normal amounts, 0.20 to 0.75 percent, it has little apparent effect on the tensile properties of steel at room temperature. In some grades of steel, silicon is added in larger than normal amounts as an alloying element, particularly in combination with other elements.

Phosphorus. In amounts up to a maximum of 0.05 percent, phosphorus has no practical effect on the structure or properties of steel.

The **sulphur** content should be kept as low as possible. When steel is deoxidized with critical amounts of aluminum, the sulphide inclusions are responsible for a falling off of the ductility.

When present in moderate amounts (0.50 to 5.00 percent), **nickel** produces a fine-grained structure and imparts strength, toughness, and, to a lesser degree, hardness, without decreasing ductility.

Although **chromium** is generally used in conjunction with an additional alloying element, simple chromium cast steels may be given properties far superior to those of carbon steels. With a given carbon content, chromium increases the tensile strength and yield point, but at the expense of some ductility. Castings subject to abrasion, corrosion, or high operating temperatures give much better service on the addition of chromium.

Because of their air-hardening qualities, **molybdenum** steels develop excellent properties in castings that must retain considerable strength and hardness, but which, because of large size or intricate design, cannot be liquid quenched. Representative compositions show molybdenum to be present from 0.20 to 0.50 percent. It finds application in castings requiring high tensile properties at moderate temperatures.

Vanadium is added to cast steel in amounts from 0.10 to 0.30 percent to produce grain refinement upon heat-treatment. Vanadium cast steels show high elastic properties and excellent resistance to impact.

The use of 0.50 to 2.00 percent **copper** in normalized copper-cast-steels when reheated to 850 to 1050 F, shows an increase in tensile strength, yield point, and hardness due to a precipitation hardening action.

Titanium and **aluminum** are excellent deoxidizers and scavengers. They are added as a final deoxidizer to the molten metal. Aluminum should be added at the rate of 2 lb or over per ton of metal in order to prevent low ductility.

Physical Characteristics

Steel that is made for steel castings should be thoroughly deoxidized, and care should be exercised in mold condition and metal transfer so that the casting will not have porosity.

Immediately upon the introduction of the molten steel into the mold cavity, two changes in volume of the metal take place. One occurs as the metal solidifies and amounts to about a 3 percent contraction and is known as the solidifying contraction. The other occurs during the cooling of the casting to room temperature and is referred to as the solid contraction. The amount of solid contraction that takes place depends on the shape and complexity of the casting, the amount of cored construction, etc., which acts

be fed directly by an outside reservoir, instead of through the legs, the section at S_2 will be sound and contain no cavity. As the location of feed heads depends largely on the foundryman, it is safer to design a casting so as to avoid the necessity for their use.

Joined Sections. There are five ways in which sections may be joined, L, T, V, X, and Y.

In L sections, if the outside corner at the junction is maintained, an increasing radius at the inner corner will bring about an increasing size of defect. If the section is uniform throughout, a defect will be found if the inner radius is small. If the inner radius is increased, but a uniform section is maintained, the defect will become smaller until it develops into centerline weakness, a condition likely to be found in uniform sections of any length. L sections should have from ½ to 1 in. inside radius; in a few cases, a radius up to 3 in. may be used. Making the section at the junction slightly smaller than that of the arms appears to give the best results.

To avoid a contraction cavity in a T section, it is necessary to core a hole at the center of the junction of the two members. Depressions in the arm of the T, although not eliminating the defect, reduce it markedly. A radius of ½ to 1 in. is recommended.

A uniform V section will not be free from contraction cavities; a slightly reduced section at the junction of the members is necessary. An inner radius of not less than 1 in. is recommended.

An X section cannot be designed free from a contraction cavity if the section is fed only through the arms. The defect can be made quite small by designing the joining section with a cored hole. By offsetting the arms of the X the hot spot would be reduced. A section having one arm completely offset allows the foundryman to use external chills to advantage.

In a Y section, the defect is about the same size regardless of the details of design. Arrangements should be made for feeding the junction.

A study of these sections leads to the following conclusions: In unfed joining sections in L or V shapes, all sharp corners at the junction should be replaced by radii so as to make this section slightly smaller than that of the arms. In X sections, two of the arms should be offset considerably. In all joining sections, sharp corners at the junctions should be replaced by radii. In the case of unfed T and X sections, these radii should not be large.

castings, they are usually held at temperature for approximately 1 hr for each inch of the thickness of the largest section of the castings.

In quality castings, a double heat-treatment is often given. An annealing treatment at a high temperature of 1600 to 2000 F is used for a homogenizing treatment which is followed by a second treatment at a temperature only slightly above the critical temperature range to refine the grain.

When exceptional mechanical properties, high degree of structural refinement, and resistance to wear are required, heating, quenching, and tempering will greatly assist in producing the desired results.

The following is the recommended practice for the heat-treatment of carbon-steel castings and alloy-steel castings of the A.S.M. (Metals Handbook, 1936).

Single normalizing or single annealing of carbon and alloy steel castings with a carbon range of 0.15 to 0.40 (0.40 to 0.50) should be carried out at a temperature of 1600 to 1700 (1550 to 1600) F. The cooling should be in still air for normalizing and in a furnace or other medium for slow cooling until the temperature is 800 F or below, for annealing.

Reduction of area, percent	5–3	20–8	[a] 45–15

[a] Quenched, 1575 F; tempered, 800–1300 F.

The quenching temperature of carbon-steel castings of 0.15 to 0.30 (0.30 to 0.40) [0.40 to 0.60] carbon range should be 1600 to 1650 (1550 to 1600) [1500 to 1550] F. The heating time should be ½ hr per in. diam or thickness, the quenching medium water at 70 (125) [125 or oil] F. Tempering should last at least 3 hr and should be at 800 to 1350 F.

Alloy castings should be cooled in the molds to a temperature below the critical range, and should be shaken out as soon as they become black and cleaned rapidly while still warm. They should go to the annealing furnace as hot as possible.

allowed to proceed until the desired low point is reached. The bath is then usually recarburized and finally is deoxidized, generally by additions of ferrosilicon and ferromanganese or of a silicon-manganese alloy. Titanium or aluminum are often used as final deoxidizers after the addition of the preceding deoxidizers.

In the **basic process**, the phosphorus is oxidized and becomes part of the slag, which is removed. Reducing conditions then are created by the reactions caused by a second slag, which reduces the sulphur to low amounts. In the **acid process**, sand and fluor spar are used for slag formation; in the basic process, lime and fluor spar are used.

Steel castings are made in sand molds almost exclusively, although steel has been cast centrifugally in chill molds for the manufacture of guns. Two general types of sand molds are used—dry sand and green sand. In the former case, the molds are baked in an oven prior to filling them with molten metal. Considerable care must be given to the construction of molds and cores and to the study of molding sands. The sands must be refractory, strong, permeable, and workable. Many sands are used, from the natural sands to those that are synthetically bonded. Coarse sands, fine sands, well-rounded sands, angular sands, and well-graded sands are all useful for particular purposes.

Specifications for Carbon-steel Castings for Miscellaneous Industrial Uses

A.S.T.M. A27-39 (In summary form)

1. These specifications cover carbon-steel castings to be used for miscellaneous industrial purposes, as distinguished from carbon-steel castings made for railroad and high-temperature applications. Ten grades of castings are covered, *viz.:*

Grade N-1. Castings not required to be physically tested or heat-treated.
Grade N-2. Castings not required to be physically tested but required to be annealed.
Grade A-1. Castings required to be physically tested but not required to be heat-treated.
Grade A-2, B, and H. Castings required to be annealed and physically tested.
Grade A-3, B-1, B-2, H-1. Castings required to be full annealed and physically tested.

2. The steel shall be made by one or more of the following processes: open-hearth, electric-furnace, converter, or crucible.

3. Unless otherwise specified, all castings may be annealed one or more times and may be given a supplementary heat-treatment by tempering or drawing. Castings in any grade except A-1, A-3, B-1, B-2, and H-1 may be given a supplementary heat-treatment that includes accelerated cooling by liquid quenching, liquid spraying, or air blasting.

FIG. 3.—Tension Test Specimen for Cast Steel.

4. All castings that are to be heat-treated in any manner shall have been allowed to cool after pouring to a temperature below the critical range.

5. Chemical Composition. Steel used for the castings shall conform to the following maximum percentage requirements as to chemical composition: Mn, 1.00; P, 0.05; S, 0.06.

An analysis of each melt of steel shall be made by the manufacturer to determine the percentages of carbon, manganese, silicon, phosphorus, and sulphur. Check analysis may be made from the broken tension test specimen.

6. Tension Tests. Tension test specimens for castings of the grades that require physical testing shall conform to the dimensions shown in Fig. 3.

With increase of the annealing temperature beyond this point, the average grain size increases and the grains become larger and larger until the melting point is reached.

Starting from any annealed grain size the hardness, strength, and yield point can be increased progressively by cold working with concomitant decrease in ductility. The effects of cold working can be relieved by annealing at a suitable temperature. These are the only ways in which the properties of most non-ferrous alloys can be changed.

Precipitation Hardening. Many aluminum alloys and some alloys of copper and of nickel are hardened by a heat-treatment which is associated with precipitation from solution of a second constituent. These alloys, after heating, consist of homogeneous grains of solid solution, comparatively soft and indistinguishable microscopically from a pure metal. If cooled very slowly, the alloy will deposit crystals of a second constituent, the amount of which will increase as the temperature decreases. Rapid cooling from the solid solution zone will retain the alloy at room temperatures as a solid solution, but if the alloy is heated to a suitable temperature, particles of a new phase will form, and, in time, will grow to visible size. At some stage in this precipitation process, the hardness, strength, and (particularly) yield point of the alloy will be considerably improved. If the heat-treatment is carried out too long, the alloy becomes soft again. Hardening by precipitation involves (1) **solution heat-treatment** followed by rapid cooling and (2), precipitation heat-treatment or **aging treatment.** The temperature and time of the latter must be closely controlled to obtain the proper results. To some extent, precipitation hardening may be superimposed upon the hardness due to cold work. Precipitation-hardened alloys have an unusually high ratio of proportional limit to tensile strength, but the endurance limit is not raised nearly to the same extent.

Significance of Yield Point. The term "yield point" when applied to non-ferrous metals has a significance different from the yield point of mild steel. Few non-ferrous materials have a discontinuous break in the stress-strain curve such as produces the familiar drop of the beam in testing steel. Annealed alloys pass through a period of rather more rapid extension, but there is rarely the abrupt change that occurs with steels. Cold-worked materials commence imperceptibly to pass from the proportional state into the plastic range, and the whole stress-strain curve up to maximum stress is smooth. In testing material of this sort, two arbitrary figures are referred to as the yield strength. One is obtained by the **offset method** in which a stress-strain curve is plotted and the stress read at which the curve intersects a line parallel to the initial modulus line but distant from it by a specified amount of strain (usually 0.2 percent). The other method involves the determination of that stress which produces a specified (usually 0.5 percent) **total elongation** under load. This involves the simplest testing technique and is perfectly satisfactory for acceptance and comparative tests on a given class of material. A yield point on a non-ferrous metal without specification of offset or of strain under load is valueless.

Aluminum and Its Alloys[a]

Aluminum owes most of its applications to its light weight and the relatively high strength of its alloys, although other uses depend upon its comparatively

[a] Largely based on information supplied by Aluminum Company of America. See "The Aluminum Industry," by Edwards, Frary and Jeffries (New York, 1930) for a detailed treatment of the subject.

purposes that call for higher strength and less ductility than are typical of the other grades.

Other steel-casting specifications of the A.S.T.M. are as follows:

Alloy-steel Castings for Structural Purposes: A148-36.
Alloy-steel Castings for Valves, Flanges and Fittings for Temperatures from 750 to 1100 F: A157-39.
Austenitic Manganese Steel Castings: A128-33.
Carbon-steel and Alloy Steel Castings for Railroads: A87-36.
Carbon-steel Castings for Valves, Flanges and Fittings for High Temperature Service: A95-36.
20 Per Cent Chromium, 9 Per Cent Nickel Alloy Steel Castings (Tentative): A198-39.
Carbon-steel Castings suitable for Fusion Welding for Miscellaneous Industrial Uses: A215-40T.
Carbon-steel Castings for Fusion Welding for Service at Temperatures up to 850 F.
Alloy-steel Castings Suitable for Fusion Welding for Service at Temperatures from 750 to 1100 F.
Chromium Alloy Steel Castings: A221-39.
Chromium-nickel Alloy Steel Castings: A222-39.
Nickel-chromium Alloy Steel Castings: A223-39.

Design of Castings

Defects in castings result generally from poor design. **Hot tears** are due to large temperature differences in castings; the cracks occur at abrupt changes in section and at sharp angles. **Shrinkage cavities** are due to insufficient metal to care for metal contraction at the time of casting solidification. They are found in sections that must be fed through smaller sections.

The avoidance of hot tears requires the elimination of hot spots under stress. Hot spots occur in sections of extra mass and at positions of joining sections such as the hub of a cast wheel and the flanges or seat of a valve. All sections in a casting should, as far as possible, be made of a uniform thickness.

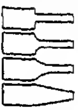

FIG. 4.—Designs Considered with Reference to Hot Tear Formation.

When the design cannot be changed to remove the hot spot, the stresses acting on the hot spots or other points of stress centralization should be diminished. Stresses usually concentrate at abrupt changes in section or at sharp corners. If liberal **fillets** replace sharp corner-junctions, the stresses will be reduced, but an increase in the radius of the fillet increases the size of the possible shrinkage cavity. Figure 4 shows improvements in design to reduce the probability of hot-tear formation.

FIG. 5.—Hot Spots.

Excessive stresses in a cast-steel structure can often be avoided by designing it in two or more parts and assembling these by **welding** or **bolting**.

When liquid steel solidifies, it contracts about 3 percent in volume, and since it solidifies progressively from the mold surface toward the center of the mold cavity, a **pipe** or **contraction cavity** will result unless the section is fed from a reservoir containing liquid steel. Castings with defects of this type may develop cracks extending from the cavity to the casting face. With an L section as in Fig. 5, a hot spot will be located somewhere near the center of the inscribed circle S_1 if the two arms of the L are of the same thickness. If, however, the L section is in a location where the junction can

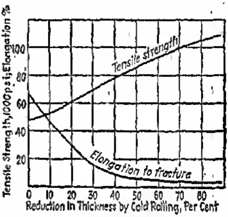

FIG. 1.—Effect of Rolling on Annealed Brass (Cu 72, Zn 28).

Cold Working and Heat-treatment

Heat-treatment. Most of the industrially important non-ferrous alloys are used either "as cast" or in the work-hardened condition. Heat-treatment for the purpose of hardening, as with steel, is not usual, but heat-treatment is nevertheless important. A cast metal consists of an aggregate of grains variously oriented and jutting one against the other. On deformation, the grains deform by a process involving the slip of blocks of atoms over each other along crystallographic planes. As this process of cold working proceeds, further deformation becomes more difficult and the metal is strengthened, hardened, and rendered less ductile. The effect of progressive cold rolling on brass is shown in Fig. 1 and may be considered as typical. With metals like copper, aluminum, and nickel, the added hardness resulting from cold work is stable at room temperature, but with lead, zinc, or tin it will disappear in time. The first effect of heating a cold-worked material is to relieve macro stresses in the object without loss of strength; indeed the strength is often increased slightly and the proportional limit raised considerably. Above a certain temperature, softening commences and proceeds rapidly with increase in temperature (Fig. 2). The old distorted grains break up into new smaller equiaxed unstrained grains. The temperature at which this occurs is lower and the resulting grain size is smaller the more extensive the working of the original piece.

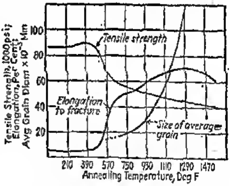

FIG. 2.—Effect of Annealing on Cold-rolled Brass (Cu 72, Zn 28).

Aluminum-copper-zinc Alloys. Alloy 3L5 is typical of a class of alloys used in Europe for general purposes. It is easy to handle, machines well, but, like all alloys containing zinc, is very weak at high temperatures. An American alloy, No. 145 of the Aluminum Co., is similar to this. This alloy is one of the best for producing sand castings with a combination of high strength and ductility without the necessity of special heat-treatment.

Aluminum-manganese alloys with about 2 per cent manganese (406) are used in places where corrosion resistance is the principal requirement, but since the casting qualities are poor, it is to a large extent being replaced by the aluminum-silicon alloys.

Permanent Mold-casting Alloys. Alloys for casting in permanent molds must be free from hot-shortness. The silicon alloys mentioned above are extensively used, also those containing copper, and alloys with both silicon and copper.

In the United States, the greater use of permanent mold castings is for internal-combustion-engine pistons for which light weight, low thermal expansion, and good properties at high temperatures are desirable. Most of these are cast in alloy 4. The more complex alloy 5 was developed primarily for this application and has a thermal expansion about 15 percent less than alloy 4, with approximately the same properties at ordinary and high temperatures and a higher thermal conductivity. Most of these alloys can be heat-treated to improve their properties or to render them less liable to dimensional change during use.

Die-casting Alloys. Aluminum alloys for pressure die-casting must possess considerable fluidity and be free from hot-shortness. The physical properties are usually of less importance than the casting qualities. Absorption of iron is difficult to avoid under operating conditions but should be kept low. There is still some use of the 8 and 12 percent copper alloys, although the trend is largely toward alloys containing silicon. A.S.T.M. specifications now include only those alloys given in Table 2.

Wrought Aluminum Alloys. Wrought aluminum alloys are divided into two classes, those hardened and strengthened by cold work alone and those which owe their improved properties to heat-treatment. Some of the latter alloys age-harden spontaneously at room temperature although others need to be heated moderately for precipitation hardening to occur. Table 3 shows the properties and compositions of wrought alloys of both types.

The most important work-hardening alloys are commercially pure aluminum (2S) or the 1.25 percent manganese alloy (3S). Both of these are available in a wide range of sheet, rod, tube, and wire sizes and extruded shapes. The latter alloy is used extensively for the manufacture of cooking utensils, conduit pipe, and other products where strength and hardness somewhat greater than those of pure aluminum are desired. Other alloys used in this class are the aluminum-manganese-magnesium alloy, 4S, and alloy 52S. These alloys can be hardened by cold work but are not heat-treated except when annealed to remove hardness resulting from cold work.

In England and Continental Europe, some other alloys are used. The most important of these are the alloys of aluminum with comparatively large amounts of magnesium. These are used in the work-hardened condition and possess properties little inferior to alloys of the duralumin type after heat-treatment.

Where a high strength alloy is necessary, it is usual to use an alloy of the **duralumin** type. The most common is 17S. This alloy is readily hot-

NOTE: Although most of the physical constants are fairly well established for the common metals, there is considerable uncertainty regarding the others. Purity has a very great effect on electrical resistivity and to a smaller degree on melting point. Specific heat, density, expansion, compressibility, and modulus are comparatively insensitive to purity and treatment.

L = linear compressibility: varies between limits shown in different crystallographic directions.

S = sublimes.

These are typical values on 0.06 in. sheet. Elongation values on thicker material are higher.

Thermal conductivity (cgs. units) is approximately (% I.A.C.S. × 0.87) + 0.03 for all aluminum alloys not containing over 5 percent silicon.

[a] Follows nomenclature of Aluminum Co. of America, except those in ( ) which are English commercial designations.

[b] O Soft annealed. ½H & H Half hard and hard (about 40 and 80 percent reduction of area of all gages, respectively). T Solution heat-treated and spontaneous aging at room temperature. W Artificially aged. RT Cold-worked prior to aging.

[c] The properties given are specification minimum, not typical values.

worked. It hardens spontaneously at room temperature after solution heat-treatment. Extensive cold working must be done within a few hours after quenching. Cold working following age-hardening is less easy but gives the highest strength obtainable with the alloys; temper RT. For aircraft construction, 17S has been largely superseded by 24S because this alloy has a higher strength. 51S has better fabricating qualities in the quenched condition. Alloy 53S is used on account of its good combination of physical properties and corrosion resistance. It is available in various rolled structural shapes; most architectural extruded sections are made from it.

The last three entries in Table 3 are typical of the strong complex alloys containing magnesium, nickel, and copper used in England. They have not gained favor in the United States.

Most of the heat-treatable alloys are rather less resistant to corrosion than is pure aluminum or aluminum-manganese alloy; alloy 53S is an exception. The corrosion resistance of the duralumin-type alloys is greatest in the quenched condition and decreases with aging at room temperature. Oil quenching and artificial aging decrease the resistance still further. Alloys 17S and 24S are available in sheet form with an integral coating of high-

good corrosion resistance, good working properties, or electrical or thermal conductivity and reflectivity.

It is produced by the electrolysis of alumina dissolved in a bath of molten cryolite. The alumina is produced by chemical refinement of bauxite, an ore containing the hydrated oxides of aluminum. Aluminum reaches the market as wrought and cast products and in the form of ingots or notched bars for remelting. The impurities (principally iron and silicon with less copper) do not exceed 0.5, or 1.0 percent, respectively, in the grades usually specified. Material of high purity is available, and metal containing over 99.99 percent aluminum can now be obtained commercially.

Commercial aluminum is a soft and ductile metal and is used for many applications where high strength is not desired. It is available in extruded or rolled forms and can be hardened by cold working but not by heat-treatment. The alloys of aluminum possess better casting and machining characteristics and better mechanical properties and therefore are used more extensively than the pure metal.

Aluminum Alloys for Sand Castings. The compositions and typical properties of aluminum alloys used for foundry work are listed in Table 2. Most of these are based on either aluminum copper or aluminum silicon systems with additions to improve the casting or service characteristics. Among aluminum-copper alloys, the one containing 8 percent copper has been used longest as a general-purpose alloy, although the additions of silicon and iron to this, CC, improve the casting characteristics, particularly in rendering the alloy less hot-short. Additions of zinc to this alloy, C, are made to improve the machinability. Alloys G and GG with 4 percent copper are comparatively weak in the cast condition but may be heat-treated to give various degrees of toughness or strength. These alloys are more resistant to corrosion than the higher copper alloys, but the precipitation treatment decreases this somewhat. The 4 percent alloys do not have so good casting properties as those containing 8 percent copper.

Alloys containing 12 percent copper are slightly stronger than the 8 percent alloy but considerably less tough. They owe their employment to the fact that it is easy to produce castings free from leaks in this alloy, although they have now been largely replaced by aluminum silicon alloys.

Alloy F, which has a small magnesium content, retains its strength and hardness up to comparatively high temperatures. It was developed primarily for pistons but is used in other high-temperature applications. It age-hardens spontaneously after casting, and further hardening may be produced by a precipitation heat-treatment at a moderate temperature, particularly if this follows a solution heat-treatment.

Alloy H, known as Y alloy, is a complex alloy, rather difficult to cast, and is susceptible to heat-treatment with the development of high strength. Although extensively used in Europe, it has found little favor in the United States. Alloy F or 6 is used for similar applications in this country.

Aluminum-silicon alloys have come into considerable use because of their excellent casting qualities and resistance to corrosion. The alloys are not hot-short and are easy to cast sound in thin or thick sections. They are rather difficult to machine. The most commonly used aluminum-silicon alloy is that containing 5 percent silicon (J). Alloy K solidifies normally with a coarse hypereutectic structure, but this is "modified" before casting by the addition of a small amount of sodium to give a fine eutectic structure of greater strength and toughness. With all alloys containing substantial amounts of silicon, the iron content must be low to avoid brittleness.

steel. In general, such tools are similar to those used for working wood but should be harder. Cemented hard carbide tools are almost essential for aluminum-silicon alloys. The casting alloys containing copper and all the wrought heat-treated alloys possess good machinability. For products in which physical properties are subordinate to high machinability, as in automatic screw machine work, alloy 11S is used, for the additions of lead and bismuth render this free-cutting.

Riveting is the most commonly used method of joining aluminum alloys, especially in structures of the heat-treatable alloys that cannot be welded without loss of strength. In general, rivets of similar composition to the base metal are used. When heat-treatable rivets are driven cold, it is important that they be used in the freshly quenched condition prior to aging, but they may be kept for long times in cold storage. Large rivets can sometimes be driven hot from their solution treatment temperature, depending on contact with tools and surrounding metal to produce an effective quench.

Welding. (See p. 1848.) The wrought-aluminum alloys are readily welded by experienced operators by either the fusion or resistance method. Fusion welding of the strong alloys is not recommended unless subsequent heat-treatment is possible, but spot and seam welding can be done if automatically controlled. Most casting alloys may be welded, but experience is necessary to overcome the danger of strains and cracks resulting from thermal contraction. Welding should be done prior to heat-treatment. The rod used should generally be of the same composition as the alloy. Aluminum alloys can be soldered, but the resultant joints are rarely satisfactory and are not recommended for highly stressed parts or for joints that cannot be given adequate protection against corrosion action.

Corrosion Resistance. Although aluminum is chemically active, the presence of a firmly adherent self-healing oxide coat on the surface prevents action except under conditions that tend to remove this surface film. Concentrated nitric and acetic acids are handled in aluminum not only because of its resistance to attack but also because any resulting corrosion products are colorless. For the same reason, aluminum is employed in the preparation of foods and beverages. Hydrochloric acid and most alkalies dissolve the protective film at the surface and permit fairly rapid attack. Moderately alkaline soaps and the like can be used with aluminum if a small amount of sodium silicate is added. Aluminum is very resistant to sulphur and most of its gaseous compounds.

Ordinary atmospheric corrosion is resisted by aluminum and most of its alloys, and they may be used without any protective coating. The pure metal is most resistant to attack, and additions of alloying elements usually decrease resistance, particularly after heat-treatment. Under severe conditions of exposure such as may prevail on shipboard or where the metal is continually in contact with wood or other absorbent material in the presence of moisture, a protective coat of paint is desirable as an added precaution.

The resistance to corrosion of aluminum alloys may be augmented by coating the material with a surface layer of high-purity aluminum or in some cases an alloy, which is rolled as an integral part of the sheet. The corrosion resistance of any of the alloys may be improved by giving an **anodizing treatment**, which comprises making the parts to be treated the anode in an electrolytic bath (chromic, sulphuric, or oxalic acid). This produces a tough adherent coating of aluminum oxide. The film will be colorless on pure aluminum and tends to be gray or colored on alloys containing silicon, copper, or other constituents. This film is very adherent and cannot be readily detached by bending or ordinary fabricating processes. If a colored finish is desired, the electrolytically oxidized article may be treated with a dye solution. Chemical methods are available for producing a similar but thinner film without electrolytic action by mere dipping in hot alkaline oxidizing solution or applying a paste.

Sand-casting alloys are covered by A.S.T.M. Specification B26-37T; Die-casting alloys by A.S.T.M. B85-39T and permanent mold alloys by A.S.T.M. B108-38T.

G & GG, J & JJ differ in impurity content but not in specified mechanical properties.

Treatments SC, CC, and DC refer to alloys in sand-cast, chill-cast, or die-cast conditions, respectively.

T4 is solution heat-treatment followed by rapid cooling and aging at room temperatures.

T6, 61, and 62 are solution heat-treatments followed by precipitation treatment.

T2, T5, T51, T571, and T59 are precipitation treatments only.

[a] Tensile properties are on ½ in. diam sand cast or ¼ in. diam chill or die-cast specimens, tested without machining surface. Yield strength corresponds to 0.2 percent offset. Endurance limit is based on 500,000,000 cycles on R. R. Moore type of machine and machined specimens. Charpy Impact is on unnotched ¼ in. square die casting.

[b] All these alloys may contain as impurities, iron in amounts not to exceed 0.4 up to 1.0 percent, silicon 0.2 to 1.2 percent, and manganese up to about 0.3 percent, according to the alloy. An intentional addition of titanium up to 0.2 percent is often made.

[c] Specification minimum values.

purity aluminum on each side; the thickness of each layer is approximately 5 percent of the total. These products, known as **alclad alloys**, possess an excellent resistance to corrosion. Because of *electrolytic action*, exposed cut edges of the base metal are protected and ordinary bare rivets may be used. The strength is slightly less than bare sheet of similar gage.

Forgings may be made under a hammer or press, using dies on such work as propeller blades, pistons, and connecting rods. Alloy 25S is generally used, but for forgings requiring the highest strength 14S can be used. Complicated forgings where the highest mechanical properties are not needed are best made of A51S.

Heat-treatment. Intermediate annealing to relieve cold work is done at a temperature of about 650 F for pure aluminum and 52S or about 750 F for 3S and 4S. The rate of cooling is unimportant. The heat-treatable alloys are best cold-worked when in the quenched condition. They may be *fully annealed only by heating to 750 to 800 F* and cooling slowly to 500 F. A partial softening can be obtained by an ordinary anneal at 650 F.

The heat-treatable alloys must have a double heat-treatment; one at a high temperature to dissolve the alloy constituents later responsible for hardening and the other at a low temperature to permit them to commence to come out of solution in the critical state that causes hardening of the alloy. The second action may take place spontaneously at room temperatures on some alloys and is then known as *natural aging*, but on other alloys it has to be carried out at a somewhat elevated temperature referred to as *artificial aging* or precipitation treatment. The correct treatment for the various alloys is given in Table 4. The solution treatment is usually done in a nitrate bath or in a furnace with forced air circulation. The temperature must be controlled closely. The solution heat-treatment of duralumin should be followed by a rapid quench, preferably in cold water since slower quenches in hot water or oil, although they minimize distortion, render the alloy susceptible to intergranular corrosion. In the alloys that age spontaneously at room temperature, hardening starts immediately after quenching and is practically complete in four days. Severe cold-forming operations must be done within less than an hour *after* quenching. If it is desired to hold the alloy for later cold-working, aging may be retarded by storing the quenched material at low temperatures, for example, in ice, which will permit working up to 24 hr, or in "dry ice" (solid CO_2) which will retard aging almost indefinitely.

The precipitation heat-treatment, if necessary, is done in a furnace with forced air circulation and heated by steam coils or electrically.

Table 4. Conditions for Heat-treatment of Aluminum Alloys

Alloy	Solution heat-treatment[a]		Precipitation heat-treatment		
	Temperature, deg F	Temper designation	Temperature, deg F	Time of aging	Temper designation
17S	930–950	....	Room	4 days	17S-T
A17S	930–950	....	Room	4 days	A17S-T
24S	910–930	....	Room	4 days	24S-T
51S	960–980	51SW	315–325	18 hr	51S-T
53S	960–980	53SW	315–325	18 hr	53S-T

[a] In a molten nitrate bath, the time varies from 10 to 60 min depending upon the size of the load and the thickness of the material. In an air furnace, proper allowance must be made for a slower rate of bringing the load up to temperature. For heavy material, a longer time at temperature may be necessary. All quenching is performed in cold water.

Machining. There are many aluminum alloys which are easily machined without special technique. Pure aluminum and the aluminum-manganese alloys are hard to machine unless special tools are used with greater rake than is customary for

When painting or lacquering aluminum it is important that the surface be properly prepared, prior to the application of the paint. A thin anodic film makes an excellent paint base, or the metal may be chemically treated with a dilute phosphoric acid solution. Where corrosive conditions are to be met, zinc chromate may be used as the pigment in the primer coat and aluminum paint for the top.

Aluminum Conductors. For electrical uses (see p. 1689), aluminum is generally unalloyed. As commercially produced in the hard-drawn condition, aluminum has a conductivity of 61 percent IACS. For power transmission lines, the necessary strength for long spans is obtained by the use of steel reinforcing cores.

Copper and Its Alloys

Copper alloys are useful on account of their heat or electrical conductivity, good cold or hot working properties, machinability, or corrosion resistance. For high thermal or electrical conductivity, commercially pure copper should be used; if greater strength is required combined with high conductivity, alloys containing cadmium or other elements are used. The cheapest copper alloy is brass of high zinc content and is used unless high corrosion resistance under stress or the special mechanical properties of other alloys are required. When good cold-working properties are desired, as in deep drawing or forming operations, a brass with 30 to 35 percent zinc is used. Leaded brass is used when much machining must be done, particularly for automatic screw machine work. For high elastic strength, the tin bronzes are used. The alloys of copper with aluminum or silicon or nickel are good for corrosion resistance.

Several hundred different copper alloys are available but requirements can generally be met satisfactorily by one or more of the standard alloys listed in Table 6.

Commercial Copper. Much high-grade copper is still made by fire refining, but the larger proportion is refined electrolytically from anodes of crude blister copper. Sometimes the copper is leached directly from the ore and the solution electrolyzed to give a pure cathode copper directly. **Lake copper** originates in the Great Lakes district; it is not electrolytically refined but is of high purity and conductivity. Secondary copper, fully equal to primary copper, is reclaimed from copper-alloy scrap. A less pure grade of copper known as **casting copper** is produced for brass-foundry use in making alloys. The electrolytic refining operation produces cathodes that may measure about 3 ft square and weigh as much as 300 lb. Cathodes may be used directly for making alloys, but if copper is to be rolled to fabricated forms, it is melted and cast into wire bars, cakes, or billets. The remelting or so-called refining operation involves melting in a large fuel-fired reverberatory furnace, oxidation to eliminate sulphur and gas absorbed from the fuel, and "poling" to reduce the oxygen to about 0.04 percent. When correctly refined, castings solidify with an approximately level surface, the gas evolved during solidification balancing the shrinkage that would otherwise occur. This is known as **tough-pitch copper**. It has a density of 8.4 to 8.7 g per cc when cast, 8.89 to 8.92 when worked and annealed.

The presence of oxygen is desirable in making the copper slightly harder and, before electrolytic refining was adopted, was useful in neutralizing the effect of certain impurities. Oxygen is harmful if the copper is to be welded or otherwise heated in a reducing gas, as it causes an embrittlement of the

Table 8 summarizes the A.S.T.M. specification requirements for 65/35 brass of various rolled and annealed tempers. Practically all wrought copper alloys

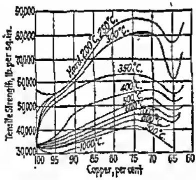

FIG. 3.—Tensile Strength of Copper-zinc Alloy.

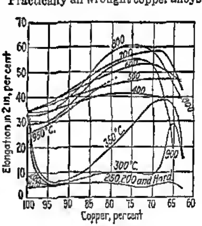

FIG. 4.—Percentage Elongation in 2 in. of Copper-zinc Alloys.

are used in the cold-worked condition to gain additional strength. Articles are often made from annealed stock and depend on the work of the forming operation to shape and harden them. When the work involved is too small to do this, brass rolled with more or less temper depending on requirements should be used.

Brass for spring purposes should be rolled as hard as consistent with the subsequent forming operations. For articles requiring sharp bends, or for deep-drawing operations, annealed brass must be used. In general, the lower grain sizes are to be preferred.

Table prepared by Technical Department of The American Brass Co. Values shown are typical and should not be used for specification purposes as they vary with shape and size tested and manufacturing variables. Tests on sheet 0.040 in. thick; rod 1 in. diam., wire 0.08 in. diam; tube 1 in. O.D. by 0.065 in. wall thickness. "Hard" sheet was reduced 4 B. & S. gage numbers in thickness by cold rolling. "Hard" rod, wire, or tube corresponds to commercial hard-drawn temper.

Higher values of yield and tensile strength and hardness are obtained by a greater amount of cold working, but this is limited to relatively narrow sheet and wire, rod, and tube of small diameter.

[a] Elongation on wire is on 10 in. gage length.

HT Precipitation heat-treatment on form shown.

F. Rockwell F hardness.

qualities, hardens them somewhat, and has given rise to the misleading name **phosphor bronze.** The bronzes are characterized by excellent elastic properties.

The **aluminum bronzes** with 5 and 8 percent aluminum find application because of their high strength and corrosion resistance, and sometimes because of their golden color. Those with 10 percent aluminum and other alloys of the type of "Tempaloy 917" listed in Table 6 with even higher amounts are very plastic when hot and have exceptionally high strength, particularly after heat-treatment.

The **copper-silicon** alloy "Everdur" listed in Table 6 may be considered as typical of its class. Other alloys (trade names, Duronze, Herculoy, Olympic Bronze, P M G Metal) are made in which zinc, iron, or tin is substituted for the manganese without a substantial change in physical properties. These alloys are as corrosion resistant as copper (slightly more so in some solutions) and possess excellent hot workability with high strength. Their outstanding characteristic is that of ready weldability by all methods. The alloys find extensive application for tanks, for chemical processing vessels and hot-water storage, fabricated by arc or acetylene welding.

The **cupronickels** and so-called **nickel silvers** are white in color and find application on this account, and because of their comparative freedom from tarnishing under atmospheric conditions. Nickel silver is the base for most silver-plated ware. The cupronickels are extremely malleable and may be worked extensively without annealing. Because of their excellent corrosion resistance, they are used for condenser tubes for most severe service. Alloys containing nickel have the best high-temperature properties of any copper alloy.

Many copper alloys capable of precipitation hardening have been proposed, but those containing **beryllium** and **chromium** are the only wrought alloys that find extensive application in the precipitation-hardened condition. The former is expensive, but its strength and elastic properties are so far superior to other materials that it is ideal for springs, diaphragms, and the like where high fatigue resistance under somewhat corrosive conditions is needed. The substitution of cobalt for part of the beryllium produces a cheaper alloy of only slightly inferior properties. Chromium copper is used either as castings or wrought shapes principally for electrodes in resistance welding machines. It has a high conductivity (about 80 percent of copper) and does not soften on prolonged heating at temperatures below about 850 F. This alloy is used in strip form for electrical switch parts because of its high softening temperature.

Young's modulus of all copper alloys in all conditions lies between 14 and 22×10^6 lb per sq in; for pure copper it is 17×10^6; for brass and bronze about 15×10^6. Nickel raises the modulus. The exact value for any alloy depends on residual stresses and to some degree on the extent and character of working that it has received. The proportional limit of any cold-worked copper alloy can be raised (sometimes very considerably) by a low temperature heat-treatment or relief anneal.

Fabrication. Practically any of the copper alloys listed in Table 6 can be obtained in sheet, rod, and wire form and many in the form of tubes. Most of them, in the annealed condition, will withstand extensive amount of cold work and may be shaped to the desired form by deep drawing, flanging, forming, bending, and similar operations. If extensive cold work is planned, the material should be purchased in the annealed condition. Very extensive operations need intermediate annealing either to avoid failure of the metal or to minimize the power consumption. This is done at 900 to 1300 F depending on the alloy, and is usually followed by air cooling. Because of the

copper and renders it useless. **Deoxidized copper** is usually made by adding phosphorus, but this decreases the conductivity. **Oxygen-free copper** of high conductivity and density is now available, made by casting without contact with air. Like deoxidized copper, this is more ductile than tough-pitch copper and is immune from embrittlement by hot reducing gases unless it has been allowed to absorb oxygen during fabrication.

Copper may be rolled extensively at any temperature up to about 1900 F but is preferably hot worked at 1600 F. **Sheet copper** for roofing is sometimes used as it leaves the rolls, but for other purposes it is commonly employed after it has been cold-rolled to increase its hardness and strength. **Copper wire** above 0.04 in. diam is commonly made by drawing from a hot-rolled rod without annealing, but smaller sizes involve intermediate anneals. Copper shapes for switch parts are made by **extrusion**, brushes and commutator sections by rolling and **drawing**. Copper for electrical purposes must be very pure; the presence of even traces of certain impurities (particularly phosphorus, arsenic, and iron) decreases the conductivity very considerably.

Copper containing small amounts of silver or antimony retains the effect of cold working to a higher temperature than pure copper (about 610 F compared with about 400 F). This is useful where comparatively high temperatures are to be withstood, as in soldering or enameling operations.

Copper for **electrical purposes** should have a minimum copper content of 99.90 percent (silver being counted as copper) and a resistance, measured on a drawn and annealed wire, not to exceed 0.15436 ohms per m-g at 20 C (A.S.T.M. specification B5-27). Selected values of the strength of copper wire from A.S.T.M. specifications B1-40, B2-40, and B3-39 are shown in Table 7.

Brasses

The useful copper-zinc alloys contain up to 40 percent zinc. Those with 30 to 35 percent find the greatest application as they are cheap, very ductile, and readily worked. With decreasing zinc content, the alloys approach copper more and more in their properties and improve in corrosion resistance. **Season cracking** may occur with high-zinc brasses but rarely with 15 percent zinc or below; this is spontaneous cracking, occurring on exposure to atmospheric corrosion, in brass objects with high residual tensile stresses at the surface. It may be prevented by avoiding the production of internal macrostresses or by removing such stresses by relief annealing at 475 to 530 F without softening the work. It should be noted that alloys susceptible to spontaneous season cracking, even if they are free from internal strains, will crack when exposed to corrosive conditions under high service stresses.

The 5 to 20 percent zinc alloys find application because of freedom from season cracking, because of their red color, and because their high melting point is desirable in brazing operations. The properties of these alloys are included in Table 6. Figures 1 and 2 show the effect of progressive cold rolling and progressive annealing on a brass containing 30 percent zinc. Cold working increases the hardness and tensile strength and decreases the ductility as measured by elongation or reduction in area. Annealing below a certain temperature has practically no effect, but in the recrystallization range a rapid decrease in strength and increase in ductility occurs. At this point, the effect of cold working is almost entirely removed. Heating beyond this point results in the growth of the grains with comparatively little further increase in ductility. Figures 3 and 4 show the variation of properties of brass with composition after annealing at the temperatures indicated.

Corrosion Resistance. All copper alloys are highly resistant to atmospheric attack but for outdoor exposure those containing over 80 percent of copper (or copper itself) are preferred because of their relative immunity from season cracking (p. 663).

Water pipes are commonly made of deoxidized copper, red brass, and yellow brass, the last being least resistant to acid waters. Alloys with over 80 percent copper, such as red brass, the silicon-copper alloys, cupronickel, or aluminum bronze, are generally more resistant to corrosion than the alloys with low copper content. Deoxidized copper, arsenical copper, or Admiralty brass have proved satisfactory for condenser tubes operating with fresh water. In sea water, copper is less suitable because of its inability to form protective films. Admiralty brass was for years the standard alloy for sea water installations; as now made it often contains minute additions of arsenic, antimony, or phosphorus to retard dezincification, which is in effect selective corrosion of the alloy with redeposition of copper. Aluminum brass and 70/30 cupronickel are preferred for the most severe sea water service.

Copper and its alloys are not suitable for use in oxidizing acidic solutions or in the presence of moist free ammonia, or mercury.

Effect of Temperature. Copper and all its alloys increase in strength slightly and uniformly as the temperature decreases from room temperatures (Table 9). No low-temperature brittleness is encountered. Copper is useless for prolonged stressed service much above 400 F, but some of its alloys may be used up to 550 F. For service above this, the cupronickel and copper-aluminum alloys alone have satisfactory properties. Aluminum bronzes, particularly those containing 10 percent aluminum, find application for valve seats in internal-combustion engines.

Tensile properties of several copper alloys at various high temperatures will be found in the A.S.T.M.-A.S.M.E. "Symposium on the Effect of Temperature of the Properties of Metals," 1931 (see pp. 425 to 427). Because of the influence of the time factor, the tensile strength is a poor indication of

Table 8. Properties of Rolled Brass
(A.S.T.M. Specification B 36-40T)

Temper	Nominal grain size, mm	Annealing temp, F, (approx)[b]	Tensile strength, psi		Rockwell hardness
			Min	Max	
Annealed A	0.120	1300	......	......	F50-62
B	0.070	1180	......	......	54-67
C	0.050	1070	......	......	61-73
D	0.035	930	......	......	65-76
E	0.025	800	......	......	67-79
	0.015	700	......	......	72-85
	Nominal reduction, B. & S. gage No.[a]	Percentage reduction of thickness			
Quarter hard	1	10.9	49,000	59,000	B40-65
Half hard	2	20.7	55,000	65,000	57-74
Three-quarter hard	3	29.4	62,000	72,000	70-80
Hard	4	37.1	68,000	78,000	76-84
Extra hard	6	50.0	79,000	88,500	82-89
Spring	8	60.5	86,000	95,000	87-92
Extra spring	10	68.7	89,500	98,500	88-93

[a] Since the B. & S. scale is a uniform geometric progression (see p. 582) the actual reduction in thickness of 1 number will decrease as the piece is progressively cold rolled, but since the actual thickness also decreases the effect of cold work remains approximately the same.

[b] The grain size obtained after a given annealing treatment is dependent on the prior grain size and on the amount of final rolling.

The addition of **lead** to brass renders it free cutting and remarkably machinable. Additions of 0.75 to 1.25 percent of **tin** improve the corrosion resistance. **Aluminum** is added to brass to improve the corrosion resistance *particularly in condenser-tube applications.* ***Manganese bronze*** *is a complex* brass. It has hot-working properties, high strength, and abrasion resistance. The related alloys, Tobin bronze and Naval brass, are used as boat shafting.

All the brasses may be hot worked if they are free from lead, particularly those alloys containing 60 percent or less of copper, for these contain a constituent beta, which is extremely plastic at high temperatures even in the presence of lead. Alloys for extrusion and hot pressing are all in this range.

Extruded sections of many copper alloys are made in a wide variety of shapes. In addition to those used architecturally for moldings, etc., extrusion is important to the engineer since many objects such as pinions, hinges, brackets, and lock barrels can be made directly from extruded bars. Special extruded shapes used as stock for automatic screw machine operations frequently reduce scrap considerably.

Bronzes

The three most common *tin bronzes* contain about 4.5, 8, and 10 percent tin and are known as grades A, C, and D, respectively. They usually contain phosphorus, from a trace up to 0.4 percent, which improves the casting

* 0.5 percent extension under load.

ready workability of brass, it is often cheaper to use than steel. Brass may be drawn at higher speeds than ferrous metals and with less wear on the tools. In cupping operations, a take-in of 45 percent is usual and on some jobs, may be larger. Brass hardened by cold working is softened by annealing at about 1100 F.

Finish. Protection of the surface is usually unnecessary with copper alloys unless freedom from tarnishing is desired. In the latter case, electrodeposited nickel and chromium is perhaps the best finish. Brass makes the best base for chromium plating as the inevitable defects in the plating do not cause rust spots. Objects in which the decorative yellow or red color of the alloy is desired are finished by transparent lacquer. Copper is the standard base metal for high-quality vitreous enamel work.

Welding. Deoxidized copper will weld satisfactorily by the oxyacetylene method. Sufficient heat input to overcome its high heat conductivity must be maintained by the use of torches considerably more powerful than those customary for steel, and preferably by preheating the work in addition. The filler rod must be deoxidized. Tough-pitch copper will not give high-strength welds because of embrittlement due to the oxygen content. Copper may be arc welded, using either metallic or carbon-arc welding with experienced operators. Filler rods of phosphor bronze or silicon bronze will give strong welds more consistently and are used where the presence of a weld of different composition and corrosion-resistance characteristics is not harmful. Brass may be welded by the oxyacetylene process but not with the arc. A filler rod of about the same composition is used, although silicon is frequently added to prevent zinc fumes.

The copper-silicon alloys typified by Everdur are characterized by remarkable ease of welding by all methods. The conductivity is not too high, and the alloy is to a large extent self-fluxing. Metallic- and carbon-arc welding are particularly easy, and if the welds are peened the strength will be equal to that of the annealed sheet. The presence of silicon aids materially the resistance welding of copper alloys.

All copper alloys, except those containing large amounts of aluminum, can be readily soft soldered or silver soldered. **Brazing** is possible only with those alloys whose melting points are sufficiently greater than that of the solder used.

Machining. See "Machining of Copper," Copper Development Association, London, 1939, and Crampton and Croft, National Metals Handbook, 1939. Free-cutting brass rod has been for years the standard material for automatic screw machine work where the very highest machinability is necessary. The use of this material will often result in considerable savings over steel at a lower base price. Most copper alloys are readily machined by usual methods using standard tools designed for steel but at higher speeds. Consideration of the wide range of characteristics presented by various types of copper alloys and the adaptation of the machining practice to the particular material concerned will give greatly improved results. For purposes of machining, copper alloys can be divided into three groups depending on their structure and related characteristics.

Group A is composed of alloys of homogeneous structure; copper, the wrought bronzes up to 10 percent tin, brasses and nickel silvers up to 37 percent zinc, aluminum bronzes up to 8 percent aluminum, the silicon bronzes, and cupronickel. These alloys are all tough and ductile and form a long continuous chip. When they are severely cold-worked, they approach the second classification in their characteristics.

Group B includes lead-free alloys of duplex structure. Some cast bronzes and most of the high-strength copper alloys in the wrought condition belong in this group. They form a continuous but brittle chip by a process of intermittent shearing against the tool edge which causes chatter unless work and tool are rigid.

Group C. Many of the basic brasses and bronzes are rendered particularly fit for machining operations by the addition of 0.5 to 3.0 percent of lead. This exists in the structure as minute uniformly distributed droplets which apparently serve the function of breaking up the chip and lubricating the tool. Chips are fine, almost needlelike, and readily removed. Very little heat is evolved, but the tendency to chatter is greater than in Type A alloy. Lead additions may be made to most copper alloys.

For lathe turning, the tough alloys of Group A need a sharp top rake angle (20 to 30 deg for copper and cupronickel; 12 to 16 deg for the brasses, bronzes, and silicon bronzes with high-speed steel tools; 8 to 12 deg with carbide tools except for copper for which 16 is recommended). Type C (leaded) materials should have a much smaller

portable tools where weight is a factor. In the United States, magnesium is produced by the electrolysis of the molten chloride extracted from salt brines of Michigan, although electrothermic processes depending on the reduction of magnesite by carbon at high temperatures are being developed experimentally. Commercially pure metal contains a minimum of 99.8 percent magnesium, a typical analysis of impurities being 0.02 percent aluminum, 0.03 percent iron, 0.002 percent manganese, 0.01 percent silicon. The pure metal is used in the chemical and radio industries, as a minor constituent in non-ferrous alloys (particularly those containing nickel, where additions of less than 0.1 percent serve as deoxidizers and desulphurizers), and as a constituent of aluminum-rich alloys, some of which contain up to 10 percent magnesium. A large and increasing amount of magnesium is used in the form of magnesium-rich alloys.

Table 13. Magnesium-casting Alloys

A.S.T.M. No.	Properties and uses	Condition	Yield strength (0.2% offset) kips	Tensile strength, kips	Elongation in 2 in., percent	Brinell hardness No.	Fatigue endurance limit, kips
	Sand-casting Alloys						
2	General purpose alloy	Sand-casting	13	22	2	54	9
		Heat-treated	12	32	7	52	10
		H.T. and aged	19	34	2	69	9
3	Strong but brittle	Sand casting	16	21	1	59	9
		H.T. and aged	21	29	0.5	78	9
4	Good properties and corrosion resistance when heat-treated. Most widely used sand casting alloy	Sand casting	12	27	5	55	10
		Heat-treated	12	38	11	55	10
		H.T. and aged	19	38	5	69	10
14	Strongest casting, not subject to shock	H.T. and aged	22	36	1	77	
	Die-casting Alloys						
12	Die-casting Alloy	Die casting	22	30	1	62	
13	Standard die-casting alloy	Die casting	21	33	3	60	
11	Max resistance to salt-water corrosion	Die casting	9	28	9	35	

Most of the alloys are with aluminum, although all contain small amounts of manganese which improves the corrosion resistance. Metal that has to be extensively worked contains about 4 to 6, forgings up to 8.5, and castings as high as 12 percent aluminum. Alloys with over 6.5 percent aluminum may be heat-treated and aged to develop increased yield strengths. Zinc additions are made to many of the sand castings and forging alloys for improved strength and corrosion resistance; silicon is added to die-casting alloys.

Table 12 lists the composition of the important magnesium alloys produced by American manufacturers, most of which are covered by A.S.T.M. specifications. The mechanical properties of these alloys in various fabricated forms

rake to minimize chatter, a maximum of 8 deg with high-speed steels and 3 to 6 deg with carbide. Type B materials are intermediate, working best with 6 to 12 deg with high-speed tools, 3 to 8 deg with carbide, the higher angle being used with the tougher materials. Side clearance angle should be 5 to 7 deg except for tough "sticky" materials like copper and cupronickel, where a side rake of 10 to 15 deg will give better service.

Many copper alloys will drill satisfactorily with the standard helix angle of 30 deg. Straight fluted tools (helix angle 0 deg) are preferable for the leaded Group C alloys. An angle of 10 deg is to be preferred for Group B and 40 deg for copper and cupronickel. Feeds may generally be 2 to 3 times those used for steel. With Type B alloy, a fairly coarse feed helps breaking up the chip, and with Type A a fine feed and high speed gives best results provided that sufficient feed be used to prevent rubbing and work hardening.

treatments are available which impart a high degree of resistance to salt water when subsequently painted. Alloys containing manganese show the greatest resistance to salt-water corrosion; this is accelerated by traces of copper and nickel.

Sand castings are made in dry sand, or in green sand to which fluorides or other substances have been added to reduce the action of water vapor on the hot metal. Shrinkage allowance is $^{5}/_{16}$ in. per ft for castings of moderate size, or $^{1}/_{8}$ in. per ft for large castings or where free shrinkage is prevented by cores or bosses. *Castings are frequently heat-treated* for severe service requirements. Die castings or permanent mold castings may be made when the initial mold cost is warranted.

Fabrication. A wide range of extruded structural sections, up to 8 in. I beams, is now obtainable. Forging and extruding and rolling operations are done at temperatures between 400 and 800 F. Sheet is often used in the cold-worked condition and will stand bends over a radius of 5 to 10 times the thickness of the sheet. Annealed sheet will bend over a radius 3 times its thickness. More severe forming operations must be carried out at a temperature of 500 to 650 F. All magnesium alloys machine with ease. High-speed steel tools are advisable or stellite or carbide tools in high production work. Top rake should be 10 to 20 deg, side rake 0 to 10 deg, and clearance 6 to 10 deg. Relatively high speed and heavy feed give best results. Tools must be kept sharp and smooth to avoid overheating of chips. Finely divided magnesium constitutes a fire hazard, and cleanliness in the machine shop is essential.

Many magnesium alloys can be welded by oxyacetylene, if the proper technique and fluxes are used. Electric spot or seam welds also can be made. Riveting is done with aluminum-alloy rivets.

service characteristics, and creep tests are greatly to be preferred. Available creep data on copper alloys is summarized in Table 10. Table 10a gives values of allowable working stresses in non-ferrous materials according to the A.S.M.E. unfired pressure-vessel code.

Copper-base Alloys for Castings

(See "Cast Metals Handbook," Amer. Foundrymen's Assoc.)

Table 11 shows the composition of the important copper-base casting alloys (mainly from A.S.T.M. Specification B30-40T), together with typical properties to be expected from sand castings.

Test results obtained on standard test pieces (either attached to the casting or separately poured) indicate the quality of the metal used, but are not identical with the properties of the casting itself because of variation of thickness, soundness, and other factors. The ideal casting is one with a fairly uniform metal section with ample fillets and a gradual transition from thin to thick parts.

Tin bronze (alloys 1A, 1B) is an excellent steam and structural bronze and is used for expansion joints, pipe fittings, gears, bolts, nuts, valves, pump pistons, casings, bushings, bearings, and in general where good strength and resistance to salt-water corrosion are required. The **leaded tin bronzes** (alloys 2A, 2B) are more machinable and somewhat more pressure-tight; these are the most commonly used alloys for steam valves and the like. All four bronzes may be used at temperatures up to 500 F. The **high-lead bronzes** (3A-3E) are used principally for bearings and bushings. **Leaded red brass** (alloy 4A), also known as "composition brass" or "hydraulic bronze," is a standard composition for general service and is satisfactory for castings to withstand hydraulic pressures up to 350 lb per sq in. It has the attributes of fairly low cost, good physical properties, good casting properties, and easy machinability. The less costly **leaded semi-red brasses** and **leaded yellow brasses** (alloys 5A, 5B; 6A-6C) are used where corrosion resistance and other requirements are less severe.

High-strength yellow brass (manganese bronze, alloys 7A; 8A, 8B) may be used for castings requiring strength, resistance to abrasion, erosion, or sea-water corrosion; examples are marine propeller hubs and blades, gears, worm wheels, gun mount castings, etc. The **aluminum bronzes** (9A, 9B) have high strength and great resistance to corrosion, shock, and fatigue. They need careful foundry practice. They are used for such castings as gun slides and mountings, worm gears and wheels, valve seats, some types of bearing, and propellers. Alloy 9B may be heat-treated by quenching from 1550 F and reheating at 700 to 1100 F for improvement of its physical properties.

The **leaded nickel alloys** (10A, 10B; 11A, 11B) are used, principally on account of their white color, in plumbing fixtures, builders' hardware, and ornamental work. Alloy 11B is also used in sand castings needing corrosion resistance and for steam valves, etc., for service up to 550 F. The **nickel-tin bronze** is a strong wear-resisting alloy. The hardness and strength may be varied greatly by heat-treatment. The properties shown are for a casting subjected to quenching from 1400 F and reheating 5 hr at 550 F. Nickel in amounts up to about 1 percent is commonly added to many of the other foundry mixtures listed in Table 11 for its effect on strength, grain refinement, and lead distribution. **Silicon bronzes** (copper-silicon alloys) have a wide range of use as sand castings because of their high strength and resistance to the corrosive action of many chemical solutions.

It is impossible to cast pure copper in the foundry. Castings for applications needing high thermal or electrical conductivity are made from copper

nickel are required and where corrosion resistance is needed in parts that have to be worked extensively.

Commercial nickel may be forged or rolled at 1600 to 2300 F. It becomes increasingly harder below 1600 F but has no brittle range. The recrystallization temperature of cold-worked pure nickel is about 660 F, but commercial nickel recrystallizes at about 1100 F and is usually annealed at temperatures between 1100 and 1750 F.

The addition of certain elements to nickel renders it susceptible to a precipitation or aging treatment to increase its strength and hardness. In the unhardened or quenched state, the alloy Z nickel fabricates almost as easily as nickel and when finished may be hardened by heating for about 8 hr at 900 to 935 F. Intermediate anneals during fabrication are at 1350 to 1750 F, and the final anneal should be at 2000 F and be followed by quenching to render the material susceptible to aging. Treatment must be in an atmosphere that will prevent loss of carbon. The increase in strength due to aging is to a great extent superimposed on that due to cold work.

Nickel castings are made in dry sand molds, but need special technique because of the high temperatures involved. The addition of 1½ percent silicon and lesser amounts of carbon and manganese is necessary to obtain good casting properties.

Alloys of nickel with 2 to 5 percent manganese are used generally for spark-plug electrodes, an application that requires resistance to hot corrosive gases. They are slightly stronger than nickel but have, in general, the same properties.

Copper-nickel Alloys. Alloys containing less than 50 percent nickel are discussed under Copper Alloys, p. 628 An important nickel-rich alloy is known by the trade name **Monel metal** (see Tables 15 and 16). It combines high strength, high ductility, and excellent resistance to corrosion. It is a homogeneous solid solution alloy; hence its strength can be increased by cold working alone. In the annealed state, its tensile strength is about 70,000 lb per sq in., and this may be increased to 170,000 in the hardest drawn wires. It is available in practically all fabricated forms. Monel metal is hot worked in the range 1850 to 2150 F after rapid heating in a reducing but sulphur-free atmosphere. It must be cold-worked in the same manner as mild steel, but requires more power. Very heavily cold-worked Monel may commence to recrystallize at 800 F, but in practice no softening will occur below 1200 F. Annealing is done in boxes for 2 to 6 hr at about 1400 F or open for 2 to 5 min at about 1725 F. Non-scaling atmospheres are desirable and sulphur-free atmospheres essential.

Because of its toughness, Monel must be machined with slower cutting speed and lighter cuts than mild steel. High-speed tools are necessary. The special grade of Monel containing sulphur ("R" Monel) should be used where high cutting speeds must be maintained. This is slightly inferior to the sulphur-free alloy in mechanical properties and corrosion resistance, and it cannot be hot forged.

The short-time tensile strength at elevated temperatures and the creep properties of cold-drawn Monel are summarized in Tables 17 and 18. Monel does not suffer impairment of properties at low temperatures as do most ferrous materials, in fact the tensile strength and yield strengths actually increase appreciably down to liquid air temperatures, although the elongation remains the same.

The fatigue endurance limit of Monel is about 37,000 (52,000) lb per sq in. when annealed (hard drawn). The action of corrosion during fatigue is

with additions of deoxidizers such as silicon, manganese, phosphorus, or zinc, which decrease the conductivity 10 to 50 percent.

Brass die castings are made when greater accuracy of dimensions or a better surface finish is required than can be obtained with sand castings. While inferior in properties to hot-pressed parts, die castings are adaptable to a wider range of design, for they may be made with intricate coring and with considerable variation in section thickness.

Where resistance to corrosion or elevated temperatures is of importance, the manufacturer of the alloy should be consulted as to its suitability under the proposed conditions.

A.S.T.M. Tentative Specifications cover Sand Castings (B80-38T), Die Castings (B94-39T), Sheet (B90-38T), Forgings (B91-38T), Bars, Rods and Shapes (B107-38T).

Typical properties of many of the alloys are given in *Proc. A.S.T.M.*, 1934, 34 (ii), pp. 277–306.

Mean specific heat (68–662 F) 0.27 approx.

Of the alloys listed, those containing lead are very readily machined and no particular difficulty will be encountered with the others.

Castings of aluminum bronze and the alloys containing lead are not considered suitable for **welding**. Silicon bronze castings can be readily welded by the usual methods and brasses free from lead and aluminum can be gas-welded.

Magnesium and Magnesium Alloys*

Magnesium is the lightest metal of structural importance (density 108.6 lb per cu ft). Its principal applications are in transport construction and in

*Largely based on publication of Dow Chemical Co. See also publications of Am. Magnesium Corp.; A.S.M. Metals Handbook; Haughton and Prytherch, "Magnesium and Its Alloys," Chemical Publishing Co., N. Y.

Monel-metal castings are made from the alloys with silicon additions listed in Table 15. Casting temperatures are of the order of 2800 F, and the composition must be carefully controlled. Magnesium is added as a deoxidizer. The castings may be softened slightly by annealing if better machining properties are desired. Cast "S" Monel can be rehardened by heating to 1100 F and cooling slowly.

The **nickel-chromium alloys** possess excellent resistance to corrosion and oxidation. They are commercially available in various fabricated forms, usually in modifications containing additions of iron, copper, or molybdenum. The standard electrical resistance materials for high-temperature service are the 80-20 nickel-chromium and 60-15-25 nickel-chromium-iron alloys. The former can be operated at temperatures up to 2100 F and the latter to 1700 F. The resistivities at 77 F are 108 and 112 microhm-cm, respectively.

Magnetic Properties of Nickel Alloys. Nickel is slightly ferromagnetic but loses its magnetism at a temperature of 695 F when pure. In commercial nickel, this temperature is about 650 F. Monel is feebly magnetic and loses all ferromagnetism above 200 F. K Monel is non-magnetic down to at least −110 F. The degree of ferromagnetism and its temperature sensitivity are very susceptible to variations in composition and mechanical and thermal treatment.

Lead

Most lead is obtained from the sulphide ore, galena, by concentration, flotation, and reduction in blast furnaces. The crude lead is purified by drossing, the precious metals removed electrolytically or by washing with molten zinc (Parkes process), and the resulting lead cast into pigs. Three grades of pig lead are recognized by the A.S.T.M. specifications (Table 19).

Table 19. Composition Specifications for Lead, Percent
(A.S.T.M. Specification B29-35)

	Grade I corroding lead	Grade II chemical lead[a]	Grade III common lead	Grade IIIa common lead
Silver	0.0015 max	0.002-0.020	0.002 max	0.002 max

Lead (difference)	99.94 min	99.90 min	99.85 min	99.73 min

[a] Term applied to undesilverized lead from S. E. Missouri ores.

Corroding lead is the highest purity commercial lead and is used for making white lead. **Chemical lead** is extensively employed in chemical plants for withstanding corrosion, particularly of sulphuric acid. Its copper content confers added stiffness on it. **Common lead** is the usual grade for alloying.

Antimonial lead is used in places where greater strength is needed. For storage-battery plates, lead containing 6 to 7 percent antimony is used. In the cast condition, this has a tensile strength of about 7,000 lb per sq in.

are shown in Table 13. These are typical figures; specification values are lower.

Designs employing magnesium alloys must take into account the lower modulus value (6.5×10^6 lb sq in.), compared with other structural materials, and the higher thermal expansion coefficient. All magnesium alloys have an expansion coefficient per degree Fahrenheit of about 14×10^{-6} at 32 F and an average coefficient in the range 68 to 752 F of 16×10^{-6} per deg F.

Magnesium alloys are not resistant to acid corrosion or continued exposure to salt water but are moderately resistant to atmospheric action, particularly if they are given a surface treatment in an acid dichromate pickle such as is usually applied to practically all fabricated forms supplied by the producers. The treated surface forms an excellent paint base. Several other chemical

the linotype machine, the metal must be fluid and capable of rapid solidification; hence metal of very nearly eutectic composition is used. It is very rarely used as the actual printing surface and therefore need not be as hard as stereo- and monotype metals. Foundry type is used for hand setting and needs greater hardness to withstand handling and repeated use.

Zinc and Zinc Alloys[a]

Zinc, one of the least expensive non-ferrous metals, is produced from sulphide, silicate, or carbonate ores by a process involving concentration and roasting followed either by reduction of the zinc ore by carbon and simultaneous distillation of the zinc in batch or continuous retorts or by leaching out the oxide with sulphuric acid and electrolizing the solution after purification. Distilled zinc contains impurities (principally Pb, Cd, and Fe) that may be eliminated by fractional redistillation to produce zinc of 99.99+ percent purity. Metal of equal purity can be produced by the electrolytic process. Zinc reaches the market in the form of slabs, 1 to 1½ in. thick, 8½ to 10 in. wide, 18 to 20 in. long. In this form, it is frequently called **spelter.**

The important grades of zinc available in the United States are covered by A.S.T.M. specification B6-37. The composition requirements are as follows:

Table 22. A.S.T.M. Specification B6-37 for Slab Zinc

Grade	Max percent			
	Lead	Iron	Cadmium	Sum of lead, iron, cadmium
Special high grade	0.007	0.005	0.005	0.010
High grade	0.07	0.02	0.07	0.10
Intermediate	0.20	0.03	0.50	0.50
Brass special	0.60	0.03	0.50	1.0
Selected	0.80	0.04	0.75	1.25
Prime western	1.60	0.08		

The special high-grade zinc is used in the manufacture of die castings, where impurities have a marked harmful effect on corrosion resistance and dimensional stability. Galvanizing (which consumes by far the largest proportion of zinc) utilizes principally Prime Western zinc. All grades are used for rolled-zinc products as the presence of impurities is often desirable for their strengthening effect. For brass manufacture and other alloys, there is an increasing tendency towards the use of high grades of zinc.

Rolled Zinc. Zinc rolled in the form of sheet, strip, or plate of various thicknesses is used extensively. Such zinc is unalloyed except for the presence of impurities resulting from incomplete refining. It is produced by hot rolling unless some stiffness and temper are required, in which case one or more of the finishing passes are done cold. The softer purer grades of zinc are used for deep drawing or forming operations, and the less pure metal is used for weather strip, roofing, and other applications where some stiffness is necessary, or where specific chemical properties are desired, as in photo-engravers' plates.

[a] Largely based on data supplied by The New Jersey Zinc Co.

Nickel and Nickel Alloys*

About 85 percent of the world's production of nickel comes from the sulphide deposits in Ontario. The smelting process involves the production of a matte containing both copper and nickel and repeatedly resmelting this with sodium sulphide to cause a separation into two layers of sulphide, one rich in nickel. The roasted sulphide may be reduced with carbon, cast to anodes, and electrolyzed to the pure metal, or reduced and vaporized as gaseous nickel carbonyl to be subsequently decomposed to form nickel pellets. If necessary, the nickel is remelted and cast as block or shot. If it is to be rolled, it is cast in ingot molds.

Monel, an important alloy of nickel, is made by reducing the copper-nickel matte without separating the metals from each other. Other alloys are made in the usual way by incorporation of the elements in the molten state.

The nominal composition and typical properties of nickel and various nickel-rich alloys are summarized in Tables 15 and 16.

Table 16. Mechanical Properties of Nickel and Its Alloys

The A.S.T.M. specification B86-38T calls for a maximum percent of 0.1 iron, 0.007 lead, 0.005 cadmium, 0.005 tin in alloys XXIII and XXI. The same impurity limits hold for alloy XXV with the exception of the tin limit, which is set at 0.002 maximum. The low limits of impurities are necessary to avoid disintegration of the castings by intergranular corrosion under moist atmospheric conditions. The presence of magnesium prevents this effect if the impurities are not higher than the specification values. The mechanical properties in Table 23 are average figures for die-cast tensile-test pieces of 0.25 in. diam or impact specimens 0.25 in. square. Specification values for these properties, if used, would naturally be lower than the typical ones quoted, and, in the case of the actual castings, considerable variations must be expected.

The alloys containing copper are stronger and possess improved corrosion resistance but are more subject to changes of dimension and properties (particularly impact resistance) on aging. Where extreme stability is important, the copper-free alloy should be used.

A measurement of the expansion of the die casting after exposure to water vapor at 203 F for 10 days is a suitable index of stability and freedom from susceptibility to intergranular corrosion and is frequently specified as an acceptance test. Analysis for impurity content is, however, more widely used.

Aging of Die Castings. Because of changes occurring in the structure of zinc die castings, they commence to shrink immediately after removal from the mold, the change being about two-thirds complete in 5 weeks. The maximum extent of this is about 0.001 in. per in. In the alloys containing copper, this is followed by an expansion. A.S.T.M. XXI alloy has a resultant expansion as much as 0.004 in. per in., whereas in alloy XXV the expansion amounts to only 0.001 in. per in. In alloy XXV, this change requires a period of many years at room temperatures. It is greatly accelerated at elevated temperatures. Coincident with expansion is some loss of impact resistance. Alloy XXI has a normal impact strength of 20 ft-lb on a 0.25 in. square casting, which drops to 3 ft-lb on dry aging at room temperature for 5 years and to about 1 ft-lb on accelerated aging. Alloy XXIII (copper-free) is unaffected by either treatment, and alloy XXV, with 1 percent copper, is

[a] Clark and White, "Symposium on Effect of Temperature on Metals," *A.S.T.M.-A.S.M.E.*, 1931, p. 383.

much less drastic on Monel than on steels of equal or higher endurance limit. McAdam found a limit of 30,000 lb per sq in. in brackish water.

Monel may be welded by the usual electric and gas methods but needs special fluxes. The gas flame should be slightly reducing and the work done rapidly without rewelding. Flux-coated electrodes should be used for arc welding. Spot and seam welding can be used on thin sheet. Soft soldering, brazing, and silver soldering are readily applied.

Monel is highly resistant to atmospheric action, sea water, steam, foodstuffs, and many industrial chemicals. It deteriorates rapidly in the presence of moist chlorine and ferric, stannic, or mercuric salts in acid solutions. It must not be exposed when hot to molten metals, sulphur, or gaseous products of combustion containing sulphur.

If about 2.75 percent aluminum is added to the base 70/30 nickel-copper alloy, it becomes susceptible to precipitation hardening. This alloy (trade name K Monel) is available in rod, strip, and wire form. It is sufficiently ductile in the annealed state to permit drawing, forming, bending, or other cold-working operations but work hardens rapidly and requires more power than mild steel. It is hot worked at 2150 to 1700 F and should be cooled and quenched from about 1450 F if the metal is to be further worked or to be hardened. Heat-treatment consists of quenching from 1450 F, cold working if desired, and reheating for 10 to 16 hr at 1080 to 1100 F. If no cold working is intended, the quench may be omitted on sections less than 2 in. thick and the alloy partially hardened during cooling from 1450 F. The properties of the heat-treated alloy remain quite stable, at least up to 1000 F for several months.

Other cobalt-chromium-tungsten alloys, usually with less tungsten than the above, find extensive application as **hard facing materials** which are applied by fusing with an oxyacetylene flame on to the edges and surfaces of parts that are subject to severe erosion or abrasion. Cast tungsten carbide and various nickel-chromium-boron compounds are also used for hard facing. These are applied in fragments or small pieces that are welded to the underlying metal with a suitable welding rod, or a composite rod is applied in a pasty condition.

Fusible Alloys

The more important fusible alloys are listed in Table 24 together with their melting points. These alloys are used as fusible links in sprinkler heads, electric cutouts, etc., for making castings in organic molds, for patterns in making match plates, for setting punches in multiple dies, and various other uses. They can be cast against wood, paper, and other organic materials without damaging them and against hard steel without drawing its temper. Many of the alloys may be used for making seals against glass. Those of lowest melting point can be melted in boiling water, a property made use of in bending thin wall tubing and forming objects from sheet which are filled with the alloy, to be subsequently melted out. Alloys containing about 50 percent bismuth undergo practically no change of volume on solidification.

For sprinkler heads with a rating of 160 F, the quaternary eutectic is used, for 200 F the bismuth-lead-tin eutectic, for 286 F the bismuth-tin, and for 360 F the lead-tin eutectic. It should be noted that intermediate temperatures between the various eutectics are not obtainable. Alloys of true eutectic composition will melt sharply at the temperatures shown and be completely solid just below it. Alloys not of the correct composition will be pasty over a range of temperatures.

[a] Selected from Booklet B-5 "Fusible Alloys Containing Tin" published by International Tin Research Council, 1937. Wood's metal is often made up roughly in the workshop from 4 parts Bi, 4 parts Pb, 1 part Sn, 1 part Cd, which is not far from the ideal composition. For other low melting alloys, see Type Metals and Solders.

[b] Most useful compositions.

with an elongation of about 22 percent, density 677 lb per cu ft. Lead for sheathing telephone and electric power cables is usually made of an alloy containing about 1 percent antimony. This alloy when extruded as cable sheath and aged 1 month at room temperature has a tensile strength of 2,750 to 3,050 lb per sq in. at a testing speed of 0.25 in. per min per in. of free length, elongation 30 to 40 percent. Endurance limit 800 lb per sq in. (50 million cycles at 700 per min).

Cast lead-antimony alloys containing 6 to 14 percent antimony have a tensile strength of 7,000 to 8,000 lb per sq in. with elongation decreasing from 24 to 10 percent. Allowable fiber stresses for indefinitely long service in extruded lead and lead alloy pipe according to the Lead Industries Association are given in Table 20. The lead-antimony alloys, particularly in the range 2 to 8 percent antimony, are susceptible to heat-treatment which considerably increases their strength. This treatment is rarely employed in practice. An alloy also used for cable sheathing is ordinary chemical lead with about 0.06 percent copper. Alloys with 0.1 percent tellurium or 0.01 to 0.10 percent calcium have been proposed for special purposes where higher creep and fatigue resistance are needed. Alloys with larger amounts of calcium (0.8 percent) and smaller quantities of alkali metals are used to limited extent as bearing metals.

Lead for coating steel (terne plate) and copper contains 5 to 25 percent of tin to aid adhesion to the base metal. Lead is an important constituent of alloys with tin and copper described elsewhere and of type metals.

Type Metals. The principal type metals are listed in Table 21. Considerable variations from these compositions are often made. Electrotype metal serves only as a backing to the shell and does not need to be hard. In

silver solders. The commercial range of standard compositions of silver and brazing solders as shown in Table 26 covers the range 1280 to 1600 F melting point. The special alloys listed in this table will be found desirable for purposes where the lower melting point justifies the higher cost. Alloys containing phosphorus should not be used for soldering steel or nickel-rich alloys on account of the formation of a brittle layer of phosphide.

Bearing Metals

Typical compositions and properties of some copper-base alloys are shown in Table 27. For low-speed operation under high pressures such as bridge bearing and expansion plates, hard bronzes containing up to 20 percent tin are used. These can be used only with a mating surface of hardened steel and under conditions of proper alignment. For lower loads, the tin content may be decreased to 10 percent or less. Additions of lead are made to bronzes for use under conditions where alignment and lubrication are apt to be poor. The alloy 80/10/10, copper-tin-lead, is most commonly used for general machinery. Alloy 88/10/2, copper-tin-zinc, has good casting properties and is used for housings, etc., cast with integral bearings. Chill casting gives a finer structure and is preferable to sand casting for the best bearing properties.

Copper alloys containing high lead are finding increased application. The bronzes with high lead and tin contents need skilled foundry technique if the lead is to be properly distributed. The maximum amount of lead that can be retained with ordinary foundary practice is 25 percent, with 5 percent tin. This constitutes the so-called plastic bronze which is singularly proof against poor installation and abuse. Maintaining the copper constant at 70 percent and increasing the tin up to 16 percent at the expense of the lead produces a useful series of bearing alloys that will withstand progressively higher pressures. Straight copper-lead alloys with 25 percent lead, the balance copper with small amounts of nickel or tin, are used for internal-combustion engines for high loads. Because of the softness of the alloy, it is applied at a high temperature in a very thin layer (0.02 in.) on a steel backing strip which is subsequently formed to fit the journal or backing.

Strip is usually purchased on specifications (A.S.T.M. B69-39) involving a "dynamic ductility" test, which is an Erichsen cupping test performed at press speeds (about 90 rpm). This indicates its ability to withstand forming operations, although it is not exactly related to drawing properties. An arbitrary "temper" test is also used which measures spring back after a definite deformation at a prescribed speed. Creep tests at room temperature are necessary to estimate the behavior of the metal under service stresses. Zinc should not be used in applications where high continuous stresses are involved.

Alloys of zinc containing 0.65 to 1.25 percent copper are significantly stronger than unalloyed zinc and possess good ductility and working properties. They can be work hardened and may be employed for parts that must withstand loads somewhat higher than would be permissible in unalloyed zinc. The addition of about 0.01 percent magnesium (*Trans. A.I.M.E.*, 1930, p. 481) to this alloy increases the creep resistance considerably, and the alloy finds some application for roofing and the like with design stresses up to 10,000 lb per sq in. Magnesium additions, however, decrease the ductility and general fabricating characteristics.

The usual tensile test is practically meaningless with zinc because the creep that occurs even at quite small loads causes the breaking load to vary with testing speed: the results are unrelated to service conditions. The speed in tensile testing is usually controlled at 0.25 in. per min under which conditions the soft grades of rolled zinc will have a tensile strength of 16,000 to 19,000, hard-rolled impure zinc 19,000 to 26,000, and the zinc-copper-magnesium alloy in the cold-worked condition as much as 50,000 lb per sq in. The elongation will vary between 5 and 65 percent but bears no direct relation to formability because of the different speed of testing. The properties of zinc vary with the direction of testing, and the across-grain tensile values will be approximately 20 percent higher than those obtained with the direction of the grain, although the elongations are correspondingly lower.

Zinc strip or sheet can be fabricated by the usual methods, **cupping, forming**, etc., provided it is not at too low a temperature. A take-in of 42 percent on the first cupping operation is usual. Warm soapy water is widely used as a lubricant. The soft grades are self-annealing at room temperature, and only the harder alloys need intermediate annealing between operations as most other metals do. When necessary, the hard zincs are annealed at 212 F and the zinc-copper alloys at about 440 F. Welding is possible, and soldering is exceptionally easy. Simple extrusion of rods, molding, and tubing is possible but expensive because of the slow speeds necessary. The impact extrusion process, however, is being more and more widely used for producing battery cups and similar articles.

Zinc is resistant to atmospheric **corrosion** but is attacked by acids and alkalies. Soap tends to inhibit the action of water. Surface finishes for corrosion resistance or improving the appearance are readily applied. These include electroplating with copper, nickel, and chromium, lacquering, enameling, or chemically coating.

Zinc Die Castings. Zinc alloys are particularly suited for making die castings since the melting point is reasonably low, resulting in long die life even with ordinary steels, and a high accuracy and good surface finish is possible.

The alloys at present used for die castings in the United States are practically limited to the three which are covered by A.S.T.M. specification B86-38T. Nominal compositions and typical properties of die-cast test pieces are given in Table 23.

hardest babbitt and when well seated gives the best service. It should not be used with soft steel for wear will occur against the hard tin-copper constituent present. No. 4 with 10 percent lead is an economical bearing for general machinery purposes. Nos. 5 and 6 are intermediate alloys containing still higher lead content and are unsuited for operations at moderately elevated temperatures. They are not widely employed. Nos. 7 to 12 are all lead-base alloys and constitute the cheapest of all bearing materials. They should contain no copper, but all the tin should be combined with antimony. They may be used for light service under comparatively high speeds if properly fitted. In general, their bearing value increases with an increase of tin content. All lead-base metals may be mated with soft steel.

Cadmium-base bearing metals find application in fields similar to the copper-lead type for severe service in internal-combustion engines. They consist of cadmium alloyed with about 1.25 percent nickel or 1.25 percent silver and 0.25 percent copper and are applied as a thin coating on steel backing or strip. These metals owe their superiority to the fact that they retain their properties up to comparatively high temperatures.

Table 28. Composition and Properties of White Metal Bearing Alloys (Babbitt Metal)

The compression test specimens were cylinders 1.5 in. long and 0.5 in. diam machined from chill castings 2 in. long and 0.75 in. diam. Brinell tests (10 mm ball, 500 kg applied for 30 sec) made on bottom machined face of specimens cast in 2 in. diam × 5/8 in. deep steel mold at room temperature.

From A.S.T.M. Standards, 1939, p. 679.

Porous Bearings. For medium-duty application in small-size bearings, bushings are made by pressing mixtures of copper, tin, and (often) graphite powder together and sintering these in a reducing atmosphere without melting. By controlling the conditions under which they are made, porosity may be adjusted so that distributed voids of up to about 30 percent by volume may be left for lubricating oil. Once impregnated with oil, these bearings will operate for long periods without lubrication. They are best used for simple cylindrical or disk shapes in quantity production.

not greatly affected at room temperature. Alloy XXIII may be partly stabilized with respect to shrinkage by heating for 3 to 5 hr at 212 F. The castings should be at temperature for this period of time and may be cooled normally in air to room temperature.

Effect of Temperature on Zinc and Zinc Alloys. The properties of zinc and zinc alloys are very sensitive to temperature. Creep resistance decreases rapidly with increasing temperature, and this must be considered in designing articles to withstand continuous loads.

Ductility and general fabricating characteristics increase with temperature. Forming and drawing operations on strip or sheet zinc should not be attempted below 70 F, and the more severe operations can be performed more readily at somewhat higher temperatures (up to 125 F).

Zinc and zinc alloys become somewhat brittle below the range 0 to 32 F, depending on the particular composition, but recover their normal properties on reaching room temperature again. Even at low temperature, the die-casting alloys have residual impact strength superior to ordinary cast iron.

Tin

The principal deposits of tin ore are in the Federated Malay States, Dutch East Indies, and Bolivia, with China and other countries contributing smaller quantities. The principal smelters are in the Strait Settlements, England, Belgium, and China. The concentrated oxide ore is reduced with carbon in reverberatory or blast furnaces, purified by liquation for the ordinary grades of tin or electrolytically or by chemical processes for high-purity material. Common grades of tin usually exceed 99 percent tin content, the principal impurities being lead, antimony, arsenic, and copper. Secondary tin is reclaimed principally from miscellaneous tinned iron and soldered scrap and scrap copper alloys. The largest single use of metallic tin is for making tin plate, with solder and bearing metals the next largest consumers. In making **tin plate**, the clean and pickled steel sheets are immersed in a long bath of pure tin at a temperature of 575 to 650 F at the entering side and only 10 to 15 deg above the melting point of tin where the sheets leave the bath through a layer of palm oil. **Terne plate** is steel coated with lead containing 12 to 25 percent tin, for pure lead will not adhere satisfactorily to steel.

Pewter was originally an alloy of tin and lead containing not over 20 percent of the latter element in the best practice, but it is now frequently replaced by an alloy of tin and antimony more commonly called **britannia metal**. This is stable and less likely to tarnish. A composition now being produced in rolled form for working into decorative tableware and the like is 91 percent tin, 7 percent antimony, 2 percent copper. Tensile strength is about 8,500 lb per sq in. With the exception of these alloys, solders, and white bearing metals, there are no other important tin-rich alloys. Tin is an important minor constituent of fusible alloys, bronzes, lead Babbitts, and type metals.

Cobalt Alloys

Various alloys of cobalt with chromium and tungsten possess exceptional hardness at high temperatures and hence they find application as **cutting tools**. The important tool materials known as Stellite (grades J and 3) are in the composition range 12–17 percent tungsten, 30–35 chromium, 2.25–2.75 carbon, balance principally cobalt. Stellite J has a Brinell hardness of about 600 at room temperatures; this drops only to 320 at 1470 F, at which temperature high-speed steel suffers almost complete loss of hardness. Stellite cannot be machined or worked and must be cast and ground to shape.

temperature is above the melting point of one of the constituents or products of reaction and simple liquid surface tension consolidates the mass. In the copper-tin alloys, the tin melts first and then is absorbed by diffusion to form a solid alloy. Generally, the sintered product is the final one ready for use, but not infrequently the material is machined to exact size or submitted to cold-pressing operation to improve the surface finish or accuracy of dimensions. There is considerable shrinkage during the sintering operation, but this can be anticipated when preparing the dies and the dimensions of the final product can be held accurately.

Porous bearing metals are made by incorporating with the metallic powder, volatile materials which are driven off on heat-treatment, leaving interconnected pores that are subsequently filled with oil. Other types of bearing are made by the admixture of graphite powder which remains intimately associated with the bronze. Brushes for electric motors are similarly made from copper and graphite powders.

Powder metallurgy is employed in the manufacture of tungsten, molybdenum, tantalum, and some other refractory metals of which cast ingots (because of impurity content or grain size) cannot be worked. By the methods of powder metallurgy, a bar is obtained which by swaging or rolling at suitable temperatures and, if necessary, annealing in hydrogen or a vacuum becomes quite ductile and can then be worked into any form.

Hard Carbides. One of the most important contributions of powder metallurgy is the production of cemented hard carbides for tool materials. Although melted and cast dies of tungsten carbide have found use as extrusion dies, in general the material is too brittle to be used unless made by a powder metallurgical process. The tungsten carbide (with or without admixture of tantalum or titanium carbides) is produced in finely granular form and, after mixing with cobalt powder and pressing, sintered at a temperature where a cobalt-rich constituent melts and binds the carbide particles together. (For the design, welding and brazing, grinding, and use of cemented carbides in the machine shop, see *Am. Machinist*, **83**, 1939, pp. 127–134.

Tungsten carbide is the basis of most of the tool materials. Combinations with tantalum carbide have desirable properties for certain applications and the double carbide of titanium and tungsten is also used. The carbides are made by adding carbon to powdered metal or oxide and then heating in a reducing atmosphere to a temperature in the neighborhood of 3600 F. The time and temperature must be controlled to give the proper carbon absorption and appropriate particle size. The double carbide $WTiC_2$ is made by solidifying a molten alloy of nickel containing tungsten, titanium, and carbon and extracting the nickel chemically. The carbide powder is intimately mixed with the binder by prolonged ball milling and then pressed in hard steel dies to a plain slab or ingot of appropriate thickness for use in tool tips or to a special shape. The pressure varies in the range 15 to 30 tons per sq in. The resulting compacts are quite delicate, and to permit handling they are usually presintered at about 1550 F which gives them some strength and allows them to be turned or cut to shape with ordinary tools. Shrinkage of the sintered material must be allowed for. The formed objects are then heated at a temperature in the neighborhood of 2500 F to develop their full hardness and strength. Although this sintering temperature is below the melting point of the cobalt binder, there is a ternary constituent formed that is definitely liquid at this temperature and is largely responsible for the bonding strength.

The principal use of hard carbides is for tipping lathe and other cutting tools. The shaped tips are copper-welded, brazed, or silver soldered to a

Additions of about 10 percent mercury to the bismuth-lead-tin eutectic gives an alloy melting at 140 F which is used for anatomical castings.

Solders

Soft Solders. The composition and melting points of the standard soft solders (tin-lead alloys) are shown in Table 25. A.S.T.M. specification B32-21 allows a variation of ±1 percent on tin or lead contents from the normal composition. Solders should have not over 0.08 percent copper (Class A) or 0.15 percent copper (Class B) and a total of less than 0.10 percent other impurities (except bismuth) with no aluminum. The running properties will be impaired if these are exceeded. The eutectic composition (37 percent Pb) has the lowest melting point and in general the best wetting

and running properties but is also the most expensive of the series. For wiped joints in lead pipe and cable, a wide solidification range is needed. The 95/5 tin-antimony alloy used for joining copper water pipe is said to have superior strength at hot-water temperatures. The high-melting-point soft solders are useful for the joining of objects that must be exposed to higher temperatures than are permissible with tin-lead solders. Those containing cadmium are more suitable for soldering zinc and galvanized iron than tin-lead solders. Alloys containing antimony should not be used on these materials.

Silver and Brazing Solders. There are no good alloys available for solders in the range from 600 to 1160 F which is the lowest melting point for

CORROSION

BY

McKay and Worthington, "Corrosion of Metals and Alloys," Reinhold. Burns and Schuh, "Protective Coatings for Metals," *Am. Chem. Soc. Monograph* 79, Reinhold.

General Considerations

Corrosion, in its most familiar form, is a reaction between a metal and water. It may be represented by the equation, metal + water = hydroxide of metal + hydrogen. It is electrochemical in nature, the solution of the metal in water and the "plating" out of the hydrogen being accompanied by a flow of electricity. The reaction may be considered as being in two parts, the **anodic reaction,** the passing of the metal into solution, and the **cathodic reaction,** the plating out of the hydrogen. Although the anodic and cathodic areas are often so close together as to be indistinguishable, as in a uniform general corrosive attack, the anodic areas may be relatively widely separated from the cathodic areas as in localized corrosion. The principal factors that affect the reaction are as follows:

The Metal. Every metal has a certain tendency to dissolve in water, which is known as *solution pressure.* A measure of this tendency can be obtained from the electrical potential which must be applied in order to prevent any action when the metal is immersed in a solution of one of its salts of a given concentration. From such information, the metals may be arranged in a series in the order of their solution pressures. Complete agreement as to the order has not been reached. The order of the common metals with respect to decreasing solution pressure appears to be as follows: potassium, sodium, barium, strontium, calcium, magnesium, aluminum, manganese, zinc, cadmium, iron, cobalt, nickel, lead, tin, hydrogen, bismuth, copper, antimony, arsenic, mercury, silver, palladium, platinum, gold. Although this series indicates the relative tendencies of the metals toward corrosion (gold being minimum), it should be used with caution. Other factors may often greatly affect the rate of corrosion of a metal.

The Water. Water is always dissociated to some extent into its constituent ions, H^+ and OH^-. Any condition that promotes an increase in the concentration of the hydrogen ions favors the formation of hydrogen and *hence favors corrosion of iron immersed in the water.* For this reason, the solution of an acid or an acid gas in water promotes corrosion. On the other hand, an increase in the hydroxyl-ion concentration, for example, by the addition of an alkali or alkaline salt, retards or even prevents corrosion of iron. Limewater or dense cement concrete will inhibit the rusting of iron.

The hydroxide of the metal can influence directly the corrosion of the metal, while in solution, by opposing the anodic reaction, *i.e.*, the formation of more metal ions. Most of the hydroxides of the metals are relatively insoluble and have little direct bearing on corrosion. The tendency of the

Aluminum bronzes containing 8 to 11 percent aluminum with 3 to 7 percent iron are used for wearing surface for heavy duty. Unlike the leaded bronzes, they will not withstand conditions of poor lubrication. The most extensive uses of these is for bushings, guides, gears, screw-down nuts, and the like in machine-tool construction.

Table 27. Copper-base Bearing Metals[a]

[a] Many of the cast bronze alloys in Table 11 may also be used for bearings.
[b] Deformation limit is compressive stress producing permanent set of 0.001 in. on machined sand cast specimens 1 in. sq area 1 in. high.

Babbitt metal is a general term used for soft lead and tin-base metals which are used cast as liners in bronze or steel backing. In general, they are used in preference to the bronzes for higher speeds and alternating loads but are less proof against abuse. The tin-base alloys are to be preferred except where initial price is the primary consideration. The lead-base alloys lose their hardness rapidly as the temperature increases and are generally employed only for comparatively light service with good lubrication.

The important **tin- and lead-base** bearing alloys (Babbitt metal) are listed in Table 28. No. 1 is used for internal-combustion engine bearings. It is plastic and unlikely to crack but must be used in a thin layer cast on to bronze or steel backing to give suitable support. No. 2 containing more antimony is somewhat harder and less likely to pound out. No. 3 is the

The same factors, although sometimes in other guise, apply to immersed corrosion and to underground corrosion.

Factors inhibiting corrosion are: the use of a self-sacrificing metal, anodic to the metal it is desired to protect, as zinc to prevent the corrosion of iron; protective coating; the rendering of metals "passive" (or so treating them that they are insoluble in acids and do not precipitate metals from solutions); neutralization of corrosive fumes or liquids; treatment of water to render it somewhat alkaline (high pH) or to induce formation of protective surface films (as of chromate); deactivation of water by elimination of oxygen; reversed polarity to counteract the effects of stray currents; and the application of an external emf so as to render the structure cathodic and concentrate corrosion on auxiliary anodic parts used for the purpose.

Corrosion due to electrolysis, which is not to be confused with the fact that corrosion is fundamentally an electrochemical phenomenon, is generally caused by the leakage of current from electric circuits, and may take place at a point far removed from where the leakage occurs. Undue emphasis is often given to this phase of the corrosion problem. Stray currents of extremely feeble intensity and voltage may serve to accelerate corrosion, even when they have not initiated it. Corrosion due to electrolysis may be minimized by providing thorough insulation; grounding all metallic conduits; avoiding combinations of dissimilar metals in a circuit; and by maintaining apparatus in an electronegative state with reference to possible sources of current, either by a "drainage" system, or by "tying up" with some sources of current of a higher potential.

Corrosion of Metals

Iron and Steel. Under similar conditions, iron and steel corrode at practically the same rate, but the distribution of the corrosion may be different for the two. The slag interspersed through wrought iron may result in a generally distributed attack under atmospheric corrosion rather than a severely localized (pitting) attack. In underground corrosion, and in continuous immersion in water, tests have not shown so much difference between the two materials.

Polished surfaces resist corrosion much better than rougher surfaces. Variations in surface finish may have a greater influence than ordinary variations in chemical composition other than pronounced segregation. The presence of mill scale on the surface favors localized or irregularly distributed corrosion. Frequently a polished surface will withstand exposure for a considerable length of time before showing signs of corrosion.

External conditions overbalance composition of the metal in determining rates of corrosion. **Oxygen** determines the commencement of corrosion of iron and steel under ordinary conditions; it not only acts as a depolarizer but also unites with ferrous iron at the corrosion anodes. In the general absence of oxygen, corrosion drops to a negligible rate. In local absence of oxygen, a differential oxygen cell may be set up which serves to accelerate corrosion in the oxygen-poor portion. In salt solutions, corrosion depends both upon the amount of oxygen present and upon the salt in solution.

Rust may accelerate corrosion and cause pitting. The probable explanation (Evans) is that surface accumulations of rust shield the underlying metal from free access to oxygen thus rendering such portions anodic (corrodible) with respect to unshielded areas to which oxygen has freer access (cathodic areas). Under certain conditions of exposure, especially atmospheric, rust may form so continuous and adherent a coating that it protects the underlying metal from further corrosive attack. This is especially true of copper-bearing steel and iron under atmospheric exposure. Rust adheres much better to cast iron than to rolled iron or steel; the superior corrosion resistance of cast iron is attributable in large measure to this fact.

Cold working of metals results in an increased rate of attack by acids; it also increases heterogeneity in metals which may lead to increased rate of corrosion. Local cold working, as in the punching of rivet holes, builds up internal stresses and greatly

Powder Metallurgy*

The production of objects from metal powders involves (1) the production of powdered metal of suitable size and characteristics, (2) the mechanical consolidation of the powder with or without previous admixture of other metallic or non-metallic powder constituents, and (3) the heating of the pressed mass to a point where the individual particles strongly cohere by a process involving grain growth or, sometimes, fusion of one of the constituents. Powder metallurgy is valuable in producing workable ingots of extremely refractory metals like tungsten, molybdenum, and tantalum which cannot be melted without harmful contamination; in making cemented carbide tools and parts of properties superior to those when cast; and in the manufacture of alloys of components (metallic or non-metallic) which do not mix in the liquid state, such as porous (oil-filled) or graphite-containing bronzes for bearings, copper-tungsten, or silver-tungsten alloys for electrical contacts and various magnetic alloys, some of which are made with each particle insulated from its neighbors. Mechanical reasons for the use of powder metallurgical processes involve the ability to fabricate securely united articles of varying composition and properties in different parts, and the almost entire elimination of scrap in the production of small parts which would otherwise involve casting, rolling, and blanking losses. The limitations of the process lie in the facts that, compared with ordinary press operations, the processes are not so readily adapted to high-speed production methods and only comparatively small and simple parts can be pressed, since extremely high pressures are needed. Moreover, the resulting strength and ductility does not usually compare favorably with similar alloys in the cast and rolled condition.

Metal powders are produced by various methods including principally grinding in stamp or ball mills or mechanical disintegrators, granulating, atomizing, condensing metal vapors, reducing oxide powders, and precipitation by chemical or electrolytic means. Practically all the common metals and many alloys are now available in powder form. The grain size of the powder, its shape and flowing characteristics must be closely controlled for they are very important both in relation to the production of the parts and their final properties. When alloys are required, either an alloy powder may be used or, more commonly, mixed powders of the constituent metals are employed. The powder is pressed in hard-steel dies and produces the final object directly under a pressure varying between 5 and 100 tons per sq in. The powder is fed into the die automatically in carefully measured quantities. Its bulk is usually from 3 to 8 times that of the pressed part; the height of the die must allow for this. The prevention of bridging and the elimination of air is important. The pressed objects will usually have a density in the neighborhood of 80 percent of that of the solid metal. Except in the case of low-melting-point metals, the pressed compact is mechanically weak and must be handled with care.

The next operation involves heating in a neutral or reducing gas or sometimes in vacuum to a point where the desired sintering occurs. In the case of pure metals and most alloys, no part is melted during this operation but the sintering involves the growing together of the various grains by a process akin to recrystallization and grain growth in cold-worked metals. In a number of cases (hard carbides, copper-tungsten alloys), the sintering

alkalies; as the iron is weak and brittle, its use is limited to shapes cast to size. Trade names for this type of alloy are **Duriron, Corrosiron,** and **Tantiron** (see p. 589). Nickel cast iron (13 to 15 percent Ni) has high corrosion resistance toward many chemicals and to dilute acids and has the advantage of superior strength and toughness (see Table 4, p. 593).

Metals in Brine. According to the work of M. B. Smith (*Ice and Refrig.*, 12), with neutral calcium chloride brine (sp gr 1.2) copper alloys are most corrosion resistant, wrought iron, steel, and cast iron constitute an intermediate group, and lead, solder, and zinc constitute a group having lower corrosion resistance. The durability of any metal in brine, however, varies with the condition of the brine. For general purposes, a pH of 8.5 (pH 7.0 being the neutral point) is recommended. Brine with a high pH is corrosive to aluminum and zinc. The corrosiveness of a brine is increased 2 or 3 times by saturating it with air.

Calcium chloride, calcium-magnesium chloride, calcium-magnesium-sodium chloride, or sodium chloride brines, which are neutral products or even alkaline in reaction, show no appreciable difference in their attack upon metals. Magnesium chloride is to be avoided, since it may produce an acid reaction (low pH). Ammonium chloride, sometimes formed by ammonia leaking into the brine, is very corrosive to steel.

Brines should be maintained in a slightly alkaline condition by the occasional addition of milk of lime, caustic soda, or other alkali. When in proper condition, they should give the characteristic pink color with the phenolphthalein indicator. An agent, such as $K_2Cr_2O_7$, may also be used to retard corrosion although its effectiveness is lowered in a chloride solution.

Corrosion of Pipes, Boilers, and Structural Work

Pipe Materials. Tests made for the purpose of showing the relative corrodibility of iron and steel lead to the conclusion that external conditions determine the corrosion rate more than differences of composition. This has been strikingly emphasized by the soil-corrosion investigation of the National Bureau of Standards.

The presence of mill scale on pipes favors the formation of centers of corrosion, and its removal in the process of manufacture is advisable.

Removal of Oxygen from Water. In any water system, the rate of corrosion is directly proportional to the oxygen concentration of the water. In a closed system, as hot-water heating systems in which the water is used repeatedly, no appreciable corrosion normally occurs after the oxygen initially present has been used up. Removal of the oxygen (air) from water is one of the best means of eliminating corrosion of pipe and other apparatus. There are, in general, two means for doing this. The **deactivation** method consists in removing the oxygen, carried by the water, by chemically combining it with some substance before it enters the system that is to be protected. The **deaeration** method consists in the mechanical removal of the air from the water.

The **deactivation** method is generally used for hot-water heating systems. Iron or steel, which is the material used for removing the oxygen, is employed in such a form as to expose as much surface as possible. Expanded metal may be arranged so as to secure approximately 70 sq ft of exposed surface to 1 cu ft of tank space. In ½ hr at 170 F, the oxygen in water may be reduced as low as 0.3 cc per liter when fixed by chemical union with iron. The water in boilers is often treated with a substance such as sodium sulphite which unites with free oxygen.

steel shank both for cheapness and for support of the brittle tip. In designing tips, it is important to avoid large changes of thickness and to design the backer so that stresses due to thermal contraction after brazing cannot crack the tip. In designing tools, it is important to use the lowest rake angle possible so the tool may have the maximum support. Other applications of hard carbides include lathe centers, gage tips, guides of various kinds, Brinell balls, and the like. The piece should be shaped as closely as possible to final size before sintering, but a limited amount of forming can be done by grinding with special silicon-carbide or diamond impregnated wheels.

The modulus of elasticity of tungsten carbide is about 79,000,000 lb per sq in.—higher than any other known material. The compressive strength of tungsten carbide varies between 800,000 and 500,000 lb per sq in. depending on cobalt content. Thermal expansion 3.3×10^{-6} per deg F. Thermal conductivity is about 500 Btu per hr per sq ft per in. per deg F for cemented tungsten carbide, decreasing to 185 for the double tungsten-titanium carbides. A low thermal conductivity seems to favor resistance to cratering in machining steels, but in machining cast iron and other materials with discontinuous chip the high thermal conductivity and superior hardness of tungsten carbide is desirable. The lower modulus of the carbides containing tantalum or titanium (about 58×10^6 lb per sq in.) permits greater deflection before fracture than the harder tungsten carbides.

Average New York Prices of the Principal Metals 1919–1939[a]

Year	Electrolytic copper, cents per lb, New York	Lead, cents per lb, New York	Zinc, cents per lb, St. Louis	Straits tin, cents per lb, New York	Antimony, cents per lb, New York	Quicksilver, dollars per flask of 76 lb, New York	Aluminum, cents per lb, New York	Silver, cents per troy oz, New York	Platinum, dollars per troy oz, New York

solution. Constituents that may form **hydrochloric acid** are chloride of magnesium plus steam, sulphate of magnesium and the alkaline chlorides, silica and alkaline chlorides, ferric chloride, ferrous chloride, carbonate of magnesium plus chlorides, and chloride of ammonium. Constituents that may form **sulphuric acid** are normal ferric sulphate, ferrous sulphate, sulphurous acid and, ferric chloride, sulphites, hydrogen sulphide, sulphate of calcium plus organic matter, sulphate of ammonia, and sulphate of copper. Constituents that may form **nitric acid** are normal ferric nitrate, alkaline nitrates and acid sulphates or sulphuric acid, and nitrate of ammonia.

Air sucked in by the feed pumps is a cause of serious corrosion. Air bubbles, forming below the water line, may serve to localize corrosion and result in pit formation. In marine practice, it has been found advantageous to pump the water from the hot well to a filter tank above the feed-pump suction valves. The bubbles are liberated from the surface of the tank, and a head is assured for the suction end of the pump. The corrosive action of air may also be reduced by introducing the feed water into the steam space above the water line.

Both general corrosion and pitting may be reduced or practically eliminated by using an open feed-water heater to expel the air, or better still, a feed-water heater connected to a vacuum pump.

Galvanic action takes place in certain instances. The remedy for it is usually the installation of zinc plates within the boiler, which must have intimate metallic contact with the metal of the boiler. The zinc plates are corroded instead of the boiler, and the latter is protected at the expense of the former. The necessary positive contact is difficult to maintain, and the efficiency of such plates is questionable except for a relatively short period following their installation. The practice of using 1 sq ft of zinc surface for 50 sq ft of surface has been followed.

Some of the **other causes of corrosion** in steam boilers are polluted feed water containing manufacturing wastes; rain water which, through contact with acid-containing soot on roofs, etc., becomes acid in nature; water containing organic matter; certain alkaline waters, the addition of barium chloride to which would probably be advisable; autoelectrolysis between the boiler metal and carbonaceous matter such as soot or ashes, especially around mud drums and blowoff pipes; decomposition of sulphate scale, especially calcium sulphate, with the formation of sulphuric acid (some feed waters, apparently neutral at ordinary temperatures, become acid when heated strongly); coal-pit water—generally acid; boiler metal containing much impurity, especially if segregated; and straining of the boiler metal, frequently caused by lack of proper staying, which leads to buckling of the plates.

Peculiar cracks sometimes develop in riveted joints of a boiler below the water line. Those cracks are intercrystalline in their character and are usually attributed to hydrogen embrittlement. The term **caustic embrittlement** is often applied. Caustic soda, formed from sodium carbonate in the water, acting upon the steel, while under stress as it normally is in service, is said to be responsible for this phenomenon (S. W. Parr). It is claimed that this does not occur with water containing sodium sulphate.

Corrosion has been reported as resulting from **copper** precipitated on the steel surfaces from the boiler water. Presumably the character of the water favored the solution of some copper from copper feed pipes or other brass or copper parts with which it came in contact. The dissolved copper later precipitates in metallic form on iron with which it comes in contact and in so doing induces corrosion.

The Cumberland process for protecting boilers, economizers, tanks, evaporators, etc. consists in impressing an emf so as to maintain the parts to be protected in a cathodic state. Properly distributed anodes of steel or iron are used with direct current at approximately 10 volts, and the application must be continuous. The success attained is dependent upon the current reaching all parts of the surface to be protected, and this is often difficult. A film of hydrogen over the cathodic surfaces is necessary at all times otherwise local corrosion may occur even within the sphere of influence of the applied emf. The method is not so simple as is often claimed.

hydroxides to form, under certain conditions, relatively impervious coatings or masses on the surface of the metal may often have a pronounced (indirect) influence upon the corrosion of the metal.

The Hydrogen. When a metal dissolves in water, an equivalent amount of hydrogen is set free (cathodic reaction). In an acid solution, the action is usually violent and appears as a gas; in most cases, however, the hydrogen "plates" out from the solution as an invisible film on the surface of the metal which usually retards and may prevent further action (polarization) until the hydrogen has been removed.

Oxygen of the Air. Oxygen and hydrogen unite to form water with extreme slowness under ordinary conditions, but when brought into contact with certain metallic surfaces they unite easily. Upon platinum, the reaction is very rapid, on iron much slower, and on zinc and aluminum practically negligible. It is in preventing the formation of the hydrogen film (depolarization) that the presence of oxygen dissolved in the water is so necessary to corrosion. If the cathodic reaction (the plating out of hydrogen) is facilitated, by the removal or the prevention of the formation of a film of hydrogen, the anodic reaction (the solution of the metal) is likewise facilitated. If air (oxygen) is removed from the water in a boiler or heating system, practically no corrosion, after the slight initial attack, will take place. The greater the oxygen pressure, or the more active the surface of the metal in accelerating the union of oxygen and hydrogen, the more rapid is the solution of the metal. Thus it happens that although zinc has a larger solution pressure than iron, it has a much higher overvoltage and is also more readily polarized by hydrogen than is iron; consequently, iron continues to corrode in a damp atmosphere, whereas zinc does not. When, however, zinc and iron are in contact, the hydrogen equivalent of the zinc which dissolves can and does plate out on the iron; hence, under these circumstances, the zinc continues to corrode and the iron does not.

The depolarizing action takes place with extreme ease on forge or mill scale—the magnetic oxide of iron that covers a piece of iron or steel after it has been highly heated. If this scale forms a close adherent coat, it is of value as a protecting surface; but if is ruptured at any point, corrosion at this point takes place with great rapidity, and a pit is the result. For this reason, mill scale should be removed as carefully as possible from ferrous structures exposed to corrosive conditions. An entirely secondary action of oxygen is the oxidation of the ferrous hydroxide formed by the action of the water, to produce the red ferric hydroxide which is familiar as rust.

Factors Stimulating Corrosion. Atmospheric corrosion is stimulated by a very damp atmosphere, since this maintains a film of water on the metal, an essential condition for corrosion. Other factors are: oxygen (air) dissolved in this water film; acids such as acid gases in the atmosphere or sulphur compounds from cinders, coke, coal dust, etc.; salts that dissociate in water producing an acid reaction; contact of dissimilar metals; and the presence on the metal of a depolarizing surface, such as mill scale on iron. Any condition of non-uniformity within the metal such as may arise from improper or non-uniform annealing or cold working favors corrosion. Similarly, non-uniformity in the concentration of the corrosive medium is favorable to corrosive attack. This is especially true of non-uniformity in the oxygen distribution as in a stack of sheets. Areas where the oxygen concentration is low are anodic with respect to those of higher oxygen concentration; hence, localized corrosion of such areas is stimulated.

(2) longitudinal, straight cracks of considerable length. Both are caused by high internal stress. Loss of ring in a 70:30 brass is a sign of incipient cracking. Prevention is accomplished by a stress-relief anneal, *e.g.*, 70:30 brass at 590 F; the stress may also be relieved by mechanical means, *i.e.*, by springing the tubes back and forth. By covering the surface with a thin impervious metal coat such as nickel electroplating, season cracking can be prevented but this has not proved commercially practicable.

Pumps *may be corroded by the solvent action* of the liquid passing through them. When dissimilar metals in contact are used, for example, a cast-iron body with brass glands, seats, etc., autoelectrolysis is almost certain to result when brines or other electrolytes are pumped. If it is not possible to confine the construction to one metal, the less resistant metal should be used only for easily renewable parts.

Corrosion may result from the leakage of current from the driving motor. This can be prevented by using an insulating coupling between the pump and motor shafts.

Air in the pump, either free or in solution in the liquid pumped, accelerates corrosion. Pumps should be vented so that they may be completely filled with the liquid they are handling.

Chemical Equipment. The development of corrosion-resistant steels (p. 571), of high-nickel alloys (p. 575), and of ferrosilicon alloys (p. 604) has extended greatly the uses of the ferrous materials in the chemical field. Enameled steel or iron ware is used widely, but most enamels are generally attacked by alkalies. Rubber-lined tanks and other chemical equipment together with hard rubber piping and connectors now serve a very useful purpose. The number of non-ferrous metals and alloys useful for chemical equipment is exceedingly large. Lead is widely used, and the development of lead-lined steel pipe and tanks has greatly extended its sphere of usefulness. Nickel, nickel-clad steel, and alloys high in nickel are widely used (see p. 575). Special aluminum bronzes that have been modified by the addition of some other element such as iron are now coming into use for handling acids. For certain uses, especially when natural flavors and odors must be retained, silver is used. It is also used widely in the chemical industry.

Underground Pipes. Pipes buried in the ground are sometimes corroded by the action of stray electric currents from trolley-car tracks, the corrosion manifesting itself at the points where the current leaves the pipes. They should be maintained in an electronegative relation to the tracks. Corrosion may be minimized by the use of insulating joints or by draining of the current through grounded copper conductors (see *B. of S. Bull.* 55, 72, 80).

Steel, wrought iron, cast iron, and lead often corrode severely in certain natural soils without the accelerating effect of stray electric currents. Soils containing organic or carbonaceous matter such as coke, coal, cinders, etc., or impregnated with acid wastes from manufacturing plants are highly corrosive in their action. Scofield and Stenger (*El. Ry. Jour.*, Nov. 14, 1914) found that black peaty soils and clays as electrolytes in contact with metals give rise to the following voltages: sheet iron, 0 to 0.5; steel pipe, 0 to 0.5; cast-iron pipe, 0 to 0.3; pitted cast iron, 0 to 0.7; clean cast iron, 0 to 0.15; the current leaving the metal at clean spots, returning to the impurities in the metal through the external circuit. Clean iron is therefore anodic toward impurities. *The autoelectrolysis of iron buried in soils is recurrent, since* oxygen is always present in sufficient amount to act as a depolarizer.

The N.B.S. investigation of soil corrosion [*Research Papers* 883 and 945 (1936); 982 and 1058 (1937)] has established the following facts:

Ferrous Metals. Serious corrosion underground occurs in the absence of stray currents although electrical currents, which did not originate in power plants, have been

increases corrosion rates of such parts; thorough annealing after cold working is the remedy.

Stress Corrosion. The effect of corrosion on a metal while it is under stress is often much more severe than under ordinary conditions. This is particularly true of metal members subjected simultaneously to fatigue stress and to corrosion. Under such conditions, the number of stress applications required for failure of the metal is very much less than under non-corrosive conditions. A condition of internal stress, such as may result from cold working, severe heat-treatment, local overheating as in welding, etc., may also serve to accentuate the destructive effect of what otherwise would be a mild corrosive attack. For example, hard-drawn brass tubing may crack under the action of relatively slight surface corrosion, or the heads of rivets may snap off. Tightly drawn-up bolts of certain non-ferrous metals will sometimes behave similarly.

Alloys of commercially pure iron with either cobalt, nickel, or copper in small amounts (0.25 to 0.30 percent) are more resistant to atmospheric corrosion than the original iron from which they were made; all such alloys tend to form protective rust coatings. **Manganese and copper** retard corrosion when alloyed with iron or steel. The results of extensive exposure tests of black steel sheets of different copper contents (*Trans. A.S.T.M.*, 1918–1940) have shown that for black sheets exposed to the atmosphere the presence of a small amount of copper, *e.g.*, 0.20 percent, is very advantageous. Although such materials rust readily when exposed to the atmosphere, the rusting is not progressive. Unlike the rust coating that forms on ordinary steel, the coating on copper-bearing steel is smoother, more adherent, and relatively impervious, and serves to protect the underlying metal. As with ordinary steel, the "life" of copper-bearing steel likewise varies with the conditions to which it is subjected. In A.S.T.M. tests, 16 gage sheet steel and iron have not yet failed after over 24 years continuous exposure in marine atmosphere at Annapolis, Md. In Pittsburgh, Pa., on the other hand, the life of comparison materials was not more than one-fourth as long.

According to other A.S.T.M. tests, the presence of copper in the same amounts as in the materials used in atmospheric exposure tests does not materially improve the life of steel immersed continuously in water, either in treated city water (Washington), brackish river water (Annapolis), or acid mine water (Pittsburgh). Data leading to similar conclusions concerning the life of underground structures were obtained in the soil-corrosion tests carried out by the National Bureau of Standards.

Certain low-alloy low-carbon steels with an alloy content below 5 percent (see Table 13, p. 558) have an improved corrosion resistance. These steels have a relatively high yield strength and tensile strength and permit thin sections which would not be admissible without the improved corrosion resistance.

Stainless steels (see p. 571) depend primarily on the presence of chromium for their characteristic properties. Plain chromium steels (4 to 6 percent Cr) are not of the stainless type. The original stainless cutlery steel contained approximately 13 percent and was used in the hardened form. The chromium nickel (18–8) steel, is the best known, but since it is austenitic it cannot be hardened by heat-treatment. Nitric acid does not attack it but hydrochloric and sulphuric acids do. The corrosion-resistance of 18–8 steel can be seriously impaired by improper heat-treatment, whereby the metal becomes susceptible to intercrystalline corrosion. This tendency can be overcome by proper alloying additions stabilizing the material. The 18–8 steel containing about 3 percent molybdenum is widely used in the sulphite paper industry. The 18–8 steel often does not remain bright and stainless on prolonged exposure in the atmosphere, and some care and attention are desirable for the material used for architectural purposes. In sea water, severe cases of pitting and perforation have been reported; these are usually associated with sluggish flow or stagnant water. Its remarkable corrosion resistance is attributed to a self-repairing oxide film which forms over the surface. Under conditions that favor the maintenance of this film or its re-formation, if injured, the resistance of the steel to corrosive attack is remarkable.

Cast Iron. Corrosion occurs in buried cast iron in certain types of soil. The product of this "graphitic corrosion" plugs the hole so that a pipe, if undisturbed, is still serviceable in low-pressure systems. Cast iron can be greatly improved in corrosion resistance by alloying elements, such as chromium and nickel. Silicon cast iron (13 to 14 percent Si) is resistant to most acids, and many other chemicals, though not to

Deposits of soot and fly ash assist very materially in this by adsorbing the corrosive gases in the products of combustion. These combine with atmospheric water vapor, and the corrosive attack is essentially that of a weak acid. The ordinary materials used for the construction of smokestacks do not differ very much among themselves in their resistance to the corrosive attack, although there is some indication that some of the newly developed low-alloy steels are superior.

Concrete Structures. The alkaline nature of cement assures great permanence to structural steel embedded in concrete. This has been repeatedly confirmed by the examination of the steel in reinforced-concrete buildings which have been demolished. The following information on deterioration by corrosion resulting from electrical current is from *B. of S. Tech. Paper* 18.

When current passes from an iron anode into concrete, oxides of iron form on the anode, occupying about 2.2 times the volume of the equivalent iron, and giving rise to mechanical pressure (sometimes as high as 4,700 lb per sq in.) which may result in cracking the concrete. At temperatures below 113 F, and with a potential gradient less than 60 volts per ft, this action is very slight, even in wet concrete.

Concrete near the cathode, or metal through which the current leaves the concrete, becomes softened and remains brittle and friable after drying, destroying the bond between the iron and concrete. This effect is noted at all voltages, high or low, and is due to the concentration of sodium or potassium near the cathode. The content of these elements in the cement should therefore be kept low.

Salt (NaCl), or calcium chloride, should never be added to concrete used in structures that will be subject to electrolytic action. Concrete in contact with salt water is very susceptible to electrolysis. In structures exposed to the action of salts, pickling solutions, etc., the potential gradient must be kept low. In the absence of metallic electrodes, the action of the current is similar to slow seepage, the water-soluble elements in the concrete migrating toward the cathode. Grounding of electric conductors in such a structure is equivalent to installing electrodes.

Waterproofing compounds when mixed with concrete have but little effect in preventing electrolysis. Waterproofing membranes, properly applied, are fairly efficacious in preventing the entry of earth currents. Painting or otherwise coating the reinforcing metal may minimize the danger from electrolysis, but it prevents proper bonding between the metal and the concrete.

All d-c circuits within a building should be kept free from grounds. All pipe lines entering a building should be installed with insulating joints outside the building; if passing through, they should have insulating joints on both sides of the building. If the potential drop around the isolated section is 8 volts or more, the isolated section should be shunted by a copper cable. Lead-covered cable should be kept out of contact with the building.

All metallic structures within a building should be interconnected, provided that all lines entering the building are installed with insulating joints, but they should not be grounded to any ground plate lying outside the insulating joints. Maintaining the reinforcing metal negative is worse than no protection at all.

Cinder concrete is frequently used in certain types of building construction. When the concrete is properly made and poured so as to eliminate voids adjacent to the reinforcing steel, very satisfactory service can be relied upon. If it is porous, pipes buried in it sometimes suffer severe corrosive attack by the acid-forming constituents that may be present. Proper precautions should be taken to neutralize any acidity in the cinder especially that which is in immediate contact with the pipes.

An important use of cement in preventing corrosion is the use of **cement linings for pipes** carrying water. They have proved very useful for corrosive waters such as mine drainage as well as for less severe service, as in water mains. The process is now being applied regularly to cast-iron pipe and also to steel pipe even as small as that used in ordinary water service. A special type coupling for cement-lined pipe is required. Lead-lined couplings are very useful.

Lead embedded in concrete is sometimes severely corroded as a result of free lime present. Lead shower-bath pans are a common example. Protection of the surface

Deaerators remove dissolved gases from water by mechanical means. In most deaerators, the water is agitated under suitable conditions of pressure and temperature. For deaeration at ordinary temperatures, a low-pressure or vacuum system is necessary; for higher temperatures, the system may be operated at atmospheric pressure. In many deaerators, the gas as it separates from the water is swept off by a current of steam. Water cannot be completely freed of its dissolved gas by mechanical means; 4 or 5 percent of the oxygen initially present may remain. For more complete removal, deaeration must be supplemented by deactivation. After deaeration, contact of the water with air must be prevented so far as possible; otherwise air is quickly absorbed by the water.

Boiler Tubes. Although results of tests, such as the extensive investigations by Ford (U. S. Navy) of 3 in. steel and iron boiler tubes in air-saturated distilled water at 68 to 77 F, have been interpreted as justifying a certain order of merit with respect to corrosion resistance of different boiler-tube materials, the differences are small, and would seem to have no very practical significance. Conditions external to the metal are most potent in determining the character and degree of corrosive attack.

The use of **nickel-steel tubes** (30 percent Ni) according to some authorities is economical because of their much longer life. Such tubes are not heat-treated. Tubes of **corrosion-resistant steel** (18 percent Cr, 8 percent Ni) are being used in superheaters.

The most frequent cases of tube failure are those resulting from imperfect heat transmission (mainly the result of scale). Physical imperfections in the metal, particularly such as result from non-uniform cold working (expanding, hammering, etc.), are responsible for numerous failures by corrosion.

Steam Boilers. (See p. 1018.) Corrosion in boilers may take place in three ways. **General corrosion** is the least dangerous, but the boiler must be watched closely lest it be gradually weakened to an unsafe degree. **Pitting** is readily detected as a rule and is frequently difficult to stop without a thorough search for the causes. **Grooving** is often very hard to locate before leaks take place, since such corrosion takes place at points where the metal has been bent or strained and is hidden from any but the most careful inspection. General corrosion of steam boilers may usually be traced to the water employed, but it is also associated with the action of certain **boiler feed-water compounds.**

A corrosive action resulting from the presence of acid in the water (or of oil containing fatty acids), which decomposes and causes pitting wherever the sludge can find a lodging place, may be overcome by the neutralization of the water by carbonate of soda. This should be carried to a point where the water will just turn red litmus paper blue. As a preventive, only the highest grades of hydrocarbon oils should be used.

Acidity may appear where salt water makes its way into a boiler, as may occur in marine practice from leaky condenser tubes, priming in the evaporators, etc. This acidity is caused by the dissociation and hydrolysis of magnesium chloride, hydrochloric acid and magnesium hydroxide being formed under high pressure. The acid in contact with the metal forms an iron salt, which, as soon as formed, is neutralized by the free magnesia in the water, thereby precipitating iron oxide and re-forming magnesium chloride. Where it is unavoidable that some salt water should make its way into a boiler, the water should be neutralized by milk of lime, which converts the magnesium chloride into magnesia and chloride of calcium, neither of which is corrosive, but both of which are scale-forming.

Decomposition of Boiler Waters. Under the action of heat and pressure, some waters may become corrosive by the decomposition of certain constituents carried in

The **electrolytic or cold process** consists in setting up the articles to be coated as cathodes in an electrolytic bath of soluble zinc salts, the anode being metallic zinc. Small articles are placed in metallic baskets in contact with the basket and with each other, the basket being attached to the cathode of the system. Both the acid sulphate and the cyanide bath are used, the latter particularly for small articles and, with suitable addition agents, for the recently developed "bright" coatings. The use of zinc plating on a large commercial scale has been advanced by its application to the coating of steel wire. The high ductility of the pure zinc coating obtained is the outstanding feature of such a coating. The ease of control of the uniformity and thickness is also advantageous. The coating of sheet steel by plating appears to be imminent.

In the **Schoop metal-spraying process**, a stream of very small hot metal particles (perhaps molten) formed by atomizing (by means of air or gas pressure) the molten end of a wire as it is fed into a blow-pipe flame is played over the surface to be coated. If the surface has been given a proper preliminary treatment (usually by sandblasting), a very adherent coating results, the thickness of which can be varied as desired. Very thick coatings are brittle. The imperviousness of metal-sprayed coatings can often be improved by using two or more metals in the same coating. Both metallic and nonmetallic materials can be coated by this means. Coatings of any metal available in wire form that can be melted in the flame used (oxygas for common metals, Pb, Zn, Sn, Cd, Cu, etc., oxyhydrogen or oxyacetylene for metals of high melting point, such as Ni) can be made. Metal-sprayed coatings are always porous to some extent, but they can be improved if the spraying is done by means of an inert gas instead of air. The electric-arc metal-spraying method is not as yet commercially available. Higher temperatures are available with the electric arc than with the gas method together with other advantages such as the ability to spray a coating formed of two different metals in one operation. The metal-spraying process has been used for coating with zinc of assembled structures such as bridges, radio and transmission line towers, and canal gates. Ship propellers, railway-car frames, and oil-storage tanks are other large structures which are metal sprayed. The coating of a structure, after complete assembly, is the outstanding advantage of the method. The spraying of furnace and stoker parts and superheater pipes with aluminum for protection at rather high temperature is also an important application of the method. The coating metal must usually be available in wire form, but in the **gravitas method**, metal is used in the form of a fine powder or dust. A cabinet for the semiautomatic coating of small objects is available commercially; but most articles must be handled individually.

Cadmium behaves similarly to zinc as a coating metal for iron in affording electrochemical protection from corrosion. Cadmium coatings are applied commercially only by electroplating and are preferred by many, the claim being made that a thin coating of cadmium gives the same degree of protection as a thicker one of zinc. This is true to some extent under marine conditions, but in an industrial atmosphere, where sulphur compounds are present, the useful life of cadmium coatings is shorter than that of comparable zinc coatings.

Coating with Tin, Lead, Nickel, Copper, or Chromium. Coatings of tin or of a tin-lead alloy are used principally on thin sheets of iron, being applied as a rule in a manner similar to that of the hot process of galvanizing. When so-called **terne plate** is made, a mixture of tin (25 percent) and lead

Condenser Tubes. (See Evans, *loc. cit.*) The conditions that obtain in condenser service are usually most severe in marine condensers and particularly in harbors and estuaries with contaminated water. Corrosion in land service may become a serious problem if the water is polluted by industrial wastes, mine water, etc.

Corrosion in condenser tubes may take place as a rather uniform surface attack, pits, or dezincification. The first is usually not objectionable and may be advantageous if a protective surface film is built up. Uniform thinning of condenser tubes results usually from a general dezincification or frequent harsh cleaning. Localized attack by pitting is serious and leads to perforations of the wall. Dezincification occurs in certain copper alloys usually having two microconstituents and results in conversion of the material into a weak brittle state which, in time, may cause holes. A small content of arsenic in the brass increases resistance to this form of deterioration. **Season cracking** (see p. 625 and below), the combined action of stress and corrosion, resulting in split tubes, is no longer a serious problem since brass condenser tubes are now furnished in a lightly annealed condition by manufacturers. Crosswise cracking may sometimes occur as a result of fatigue because of insufficient transverse support of the tubes. Corrosion may possibly contribute to such a failure.

There are several forms of localized attack: (1) pitting associated with surface deposits in the tube in slowly moving water; (2) impingement from air bubbles, in very rapidly moving water and occurring only near the inlet end; and (3) pitting along the length of the tube associated with erosion from suspended solids in the water. Long life of any condenser tube is dependent upon the building up, by initial corrosion, of a uniform protective surface film. A deposit on the wall surface favors electrolytic attack of the metal by shielding a portion from the action of the oxygen dissolved in the water. A condition of lower oxygen content thus obtains within the shielded areas, and such an area is anodic (corrodible) with respect to the surrounding areas to which oxygen has free access. Impingement of air bubbles at high velocity promotes rapid pitting by preventing the formation of a protective film and also in a mechanical way as shown by undercutting in the pits. The high water velocity of the modern high-speed condenser has increased the erosive effect of suspended solids in removing the protective film and thus promoting pitting. In high velocity water, an area on the downstream side of surface deposits may be severely eroded and early perforation result. Reduction of impingement and erosion can be effected by cutting down turbulence in the inlet water box. The impingement effect can also be reduced by rolling and flaring the inlet end of the tubes, the flared end being flush with the tube sheet. The insertion of a short sleeve of non-metallic material at the inlet end has proved effective in preventing impingement pitting.

The practice of coating condenser tubes with tin to prevent corrosion has been widely used. The coating is effective as long as it is intact, but when worn away in spots the attack is accelerated. Nonmetallic coatings have been used with some success, but they are not favored because of their low heat transmission.

Admiralty brass (Cu, 70; Zn, 29; Sn, 1) is extensively used for condenser tubes and for years has been the standard material for marine service. For severe service, it is being superseded by **aluminum brass** (Cu, 76; Al, 2; Zn, 22) and **cupronickel** (Cu, 70; Ni, 30) which are both resistant to impingement pitting. The cupronickel cannot suffer dezincification, and deterioration from this cause is negligible in the aluminum brass. The materials are widely used especially in foreign shipping. Arsenical copper tubing is coming into use for fresh-water or inland service where Muntz metal and Admiralty may be affected by dezincification. Red brass is also successfully used for inland service. Copper and red brass are not suitable for salt or brackish water, however. See Table 6, p. 636, for the properties of these alloys.

Season cracking of brass is associated with corrosion; it takes place in two ways: (1) by irregular cracks, commonly known as season cracking, and

few uses are soot-blowing apparatus, carbonizing boxes, furnace parts, and condenser and economizer tubes. Good results are regularly obtainable up to a temperature of 1700 F and in some cases to 1830 F. Calorizing is carried out by either a powder or a dip process. In the powder process, the parts to be treated are placed in a tight receptacle partly filled with a mixture of finely divided metallic aluminum and aluminum oxide. The air is replaced by hydrogen, and the receptacle is subjected to a high temperature for a time that depends on the depth of penetration of aluminum desired. In the dip process, the parts are fluxed, then immersed in molten aluminum, and then heated to promote alloying. This method gives a thinner coating of aluminum alloy but is much more expeditious. A calorized surface resists continued temperatures up to 1800 F but begins to burn at approximately 2000 F, whereas ordinary steel begins at about 930 F. It is not affected by ordinary oxidizing furnace conditions.

Calite, which may be considered as representative of a large class of heat-resistant alloys, is an alloy of iron, nickel, and aluminum and resists oxidization up to 2200 F for an indefinite time and, for short periods, up to 2370 F. The protective oxide formed does not snap off on quenching from extremely high temperatures. It is practically non-corrodible under ordinary conditions of exposure. Many other combinations, containing chromium and nickel as essential alloying constituents, are commercially available.

A process termed **chromizing**, similar in its operation to calorizing, uses powdered chromium or ferrochromium, the articles to be coated being heated while embedded in the powdered metal within a hydrogen or other non-oxidizing atmosphere. It has only a very limited commercial application.

Magnetic Oxide on Iron Surfaces. In the **Bower-Barff process**, the iron or steel articles to be coated are heated in a closed retort to a temperature of 1600 F, after which superheated steam is admitted. This results in the formation of red oxide (Fe_2O_3) and magnetic oxide (Fe_3O_4). Carbon monoxide is then admitted to the retort to reduce the red oxide to magnetic oxide, which is highly resistant to corrosion. Each operation takes about 20 min. The glossy black coating of magnetic oxide on **Russia iron** is produced by laying up sheets of iron with powdered charcoal between, the whole mass being then heated and hammered.

Iron and steel may also be **oxide coated** by electrolytic means, the object to be coated being made the anode (anodic oxidation) in an alkaline solution. Such coatings are primarily for appearance such as for cast-iron stove parts. Though experimentally successful, the commercial application of the process is limited. The **Chemag process**, a German development, is of this kind.

Phosphate Coatings for Rust Proofing Iron and Steel. (Eckelmann, *Chem. Met. Eng.*, Dec. 24, 1919.) In the **Coslett process**, iron or steel articles immersed for 3 or 4 hr in a boiling solution, made by mixing iron filings with concentrated H_3PO_4 (sufficient to form a paste) and then adding to weak phosphoric acid, become coated with a rust-resisting deposit of basic ferrous phosphate. This process was improved by the addition of an oxidizing agent, the **Parkerizing** process, and later by the addition of other accelerators (**Bonderizing**). The phosphate coating, in itself, affords only a very slight degree of protection against corrosion. Oiling the coating improves the corrosion-resistance greatly and imparts an attractive lustrous black appearance. Coatings of this kind are not suitable for severe out-of-doors service. Phosphating a steel surface is an excellent method of priming prior to subsequent painting or lacquering. The phosphate is applied by

detected on pipe lines. Soil conditions play a major role. Wrought iron and steel corroded at approximately the same rate, and the presence of copper in the steel did not improve its corrosion resistance. In certain soils, the corrosion rate of cast iron was greater than that of steel. The removal of mill and foundry scale from the surface did not greatly affect the rate of corrosion. Depth of pitting was directly proportional to duration of exposure in certain soils, but in others the pit depth increased very slowly after the soil conditions had become stabilized. Distribution of corrosion tended to become more uniform as the exposure period increased.

Non-ferrous Metals. No metal was found outstandingly superior under all conditions. The corrosion rate (loss of weight and depth of penetration) was, with but few exceptions, greater for ferrous than non-ferrous metals. In some soils, lead pitted severely within a few years, the purest lead being most resistant to corrosion. The presence of chlorides, bicarbonates, and sulphates in the soil retarded the rate of corrosion of lead, although in certain soils, as in tidal marshes, the rate of attack did not decrease with time. Copper and high-copper alloys corroded very slowly in most soils, the presence of sulphides being the principal accelerator of corrosion, the rate of attack being particularly high in cinders. High-zinc brass became weak and brittle by dezincification in many soils. Zinc corroded rapidly in a few soils, the rate being proportional to the duration of exposure. This limits the effective life of galvanized coatings on ferrous metals. The useful service is proportional to the thickness of the zinc coating; a coating of 2.8 oz per sq ft prevented the formation of pits for 10 years except in one very corrosive soil. Over a 10-year period, the loss of weight of galvanized steel was one-half, or less, that of the companion bare steel. **Aluminum** corroded rapidly under most of the soil conditions to which it was exposed.

Pipes buried in **mixtures of two dissimilar soils** or in two unlike soils in contact (not mixed) generally corrode more rapidly than in either of the two soils separately. Lead in a mixture or simple contact of dissimilar soils will often corrode markedly. Pipes buried in trenches fulfill these conditions of soils in contact or mixed. Metals corrode at the junction line of dissimilar soils. Cast iron in soils takes on a hard coat of rust and soil, pits being filled with carbon and black iron oxide. Lead shows both the gray and brown oxides when corroded in soils. Potentials up to 1 volt may readily be generated by placing unlike metals in a given soil or by using one metal in two dissimilar soils.

Bituminous coatings are widely used, especially natural asphalt and blown asphalt made from oil residuum and coal-tar pitch. Coatings of this last substance were somewhat inferior to others in the B. of S. investigation in that they were more susceptible to soil stresses, temperature changes, softening, and brittleness although they were more resistant to water absorption. The method of application of all such coatings is important. Dipping, brushing, and spraying methods are all used. For severe soil conditions, the coating should be reinforced by wrapping the coated pipe spirally with a strong fabric of some kind which has been impregnated with a waterproof bituminous mixture. For exceptionally severe corrosive soil conditions, pipes may be encased in concrete.

Pipes are often destroyed by the action of dissimilar metals to which they are connected, such as brass valves. Short connections, readily replaced, should be used on either side of the brass fittings.

Application of a negative potential booster to diminish potential differences in electrical rails has proved to be the most effective means of reducing electrolysis of underground iron and steel, such as gas and water mains.

Bridges, Roofs, Stacks, Etc. Iron and steel structures are corroded by the presence in the atmosphere of moisture and waste products from manufacturing and metallurgical plants such as carbon dioxide, sulphur dioxide, chlorine, ammonia, zinc and acid fumes, and soot. As a rule, they are not corroded in a dry atmosphere. To minimize the corrosive effects of gases, protective coatings (see p. 673) are used. Metal work exposed to the action of sulphur fumes should be covered with brick or with a paint highly resistant to sulphur dioxide. Bridges are now protected by means of so-called **drip floors** placed over the floor proper. The failure of **metal smokestacks** by corrosion occurs only during idle periods and particularly in the summer.

adhere firmly at all temperatures to which it will be exposed; coating shall be readily removable with cotton waste wet with kerosine; polished iron, steel, copper, or brass shall show no staining when exposed to weather at any temperature below 212 F for not less than 5 days; in the salt-spray test, no rust shall be formed in 24 hr, practically none in 5 days, and no appreciable rust in 60 days. Typical formulas are: (1) 20 g rosin of "H" grade + 100 g petrolatum (U.S.P.) + 10 cc kerosine. The rosin is melted and mixed with the hot petrolatum after which the kerosine is stirred in. Rosin greatly increases the adhesiveness of the petrolatum. Wax may be added to raise the melting point of the petrolatum if necessary. (2) 3 parts candellila wax, 6 parts "H" rosin, 50 parts petrolatum (U.S.P.). (3) 2 parts carnauba wax, 5 parts "H" rosin, 50 parts petrolatum (U.S.P.). In each case, melt the ingredients together at 255 F, stir and cool. Flow an excess over the metal surface (*B. of S. Tech. Paper*, 176 and *Circ.* 200 and 214). Lanolin is the best grease to use as a basis of slushing oils. A small amount of sodium chromate is desirable in slushing greases unless all traces of water have been eliminated.

of the lead by a bituminous coating is always recommended, and the use of alumina cement, as an added precaution, can also be recommended. Aluminum and aluminum alloys in intimate contact with plaster or cement may suffer corrosion for the same reasons. Similar precautionary measures are advisable.

Methods for Minimizing Corrosion

Corrosion may be minimized by (1) the use of a coating of protective metal such as zinc, tin, lead, nickel, or copper; (2) the production of oxide, phosphate, or similar coatings on iron and steel surfaces; (3) the application of protective paints (p. 673); and (4) rendering the surface of the metal passive.

Coating Metals with Zinc. Galvanizing. Zinc is applied to metal surfaces by the Sherardizing process, by dipping into a bath of molten zinc, by electrodeposition, or by metal spraying.

In the **Sherardizing process**, the articles, after being thoroughly cleaned by pickling and sandblasting, are placed in a metal drum together with zinc dust and heated to a temperature of from 500 to 600 F, depending on their size and shape, the drum being rotated so as to promote "rumbling" of the contents. The coating that results is not pure zinc, but an alloy of about 90 percent zinc and 10 percent iron (melting point, 1260 F approx.), and is highly resistant to corrosion. The process is especially suited for screws, bolts and nuts, chains, pipe fittings, nails, small castings, and such other articles as may conveniently be placed within the drum. The cost varies with the character of the articles coated. The term **electro-Sherardizing**, which is often used, merely connotes that the Sherardizing furnace is heated electrically. By a suitable annealing or heat-treatment, the zinc coating produced on sheet and wire by hot dipping can be converted into a very similar alloy coating. A cheap method used for nails, etc., consists in "rumbling" them in zinc dust. The coating is inferior in quality.

In the **hot process**, the articles after being thoroughly cleaned are dipped into a bath of molten zinc. The bath must be maintained at a temperature somewhat higher than the melting point of zinc, which necessitates a large fuel consumption and also results in a considerable loss of zinc (approximately 10 percent). A greater source of loss is the iron-zinc alloy (dross) which forms as a heavy sediment in the zinc bath. That portion of the zinc surface through which the material to be coated enters the zinc bath must be kept covered with a flux; ammonium chloride and zinc chloride are widely used for this. The process is used almost exclusively for sheet and pipe, and, until recently, for wire also. Exposed structural steel work, such as towers, is generally zinc coated by this means. Sheet and wire are coated by mechanical means, pipe and structural shapes by hand. Many irregular shapes (pots, vats, tubs, etc.) and small shapes (bolts, nuts, nails, screws) are coated by hand. For the latter, some means for removing excess zinc, such as centrifuges or shaking devices, is generally used. A very small percentage of aluminum renders the zinc bath very fluid and is favored by many in coating irregular shapes. One or two percent tin is often added in the coating of sheets in order to obtain a very uniform coating and to improve the surface appearance. A coating applied by hot dipping never consists of a simple layer of zinc. It is always of a composite nature, the layer adjacent to the basis metal consisting of zinc-iron alloys. This layer is relatively brittle and, thereby, imposes some limitations on hot-dipped galvanized sheet and wire for certain uses. By a recent process, formation of the alloy can be practically eliminated. A coating of 1 oz per sq ft of exposed surface is considered very suitable for most conditions of service.

Paint Oils. Pure linseed oil (see p. 721), raw or boiled, on account of rapid and hard drying, is preferable for general painting work. Refined raw oil is generally used in white paints for wooden surfaces. A mixture of raw and boiled oils is sometimes preferred in paints for metal surfaces. **Menhaden oil**, which is extracted from the menhaden fish, is occasionally used in special paints for sea exposure. This oil is apt to take dust and become darkened. **Soybean oil**, extracted from the soybean, a legume grown widely for forage, has been used as a partial substitute for linseed oil. In some cases, it has given fair results in combination with linseed oil and tung or oiticica oil in different types of paint. **Tung oil** and **oiticica oils** are (see p. 721) heat-treated with resins and used in technical and waterproofing paints. Their rapid drying to a clear, glossy film makes them valuable for such purposes. **Dehydrated castor oil** and **perilla oil** are now widely used as drying oils. **Rosin oil** and **petroleum oil** are dangerous to use in paints for the protection of wooden or steel surfaces, on account of their slow drying and tendency to check.

Paste Paints. **White-lead paste** contains approximately 9 lb of oil per 100 lb. **Iron-oxide paste** contains approximately 30 percent of oil. **Red lead** is sometimes bought in the dry form and mixed with oil but is usually purchased as a paste and then thinned. Red lead is one of the most widely used of all metal preservatives and gives good service under many conditions. Red lead containing some free litharge protects metal better than neutral red lead. The litharge forms with the linseed oil a hard water-resistant film. Combination pigment paints contain on an average 30 to 35 percent oil and 65 to 70 percent pigment. Instructions for reduction and application are given on the label.

Paint Thinners. Paints of a very heavy body or thick consistency are difficult to apply and often show brush marks after application. Such paints should be thinned with **turpentine** or other neutral thinner. **Petroleum spirits** of the same boiling point and gravity are being used in most paints with very satisfactory results.

Driers. Salts or oxides of lead, cobalt, and manganese are dissolved in oil or naphthenic acids to form driers. When these driers are added to paint, they act as catalytic agents and accelerate drying by attracting oxygen. **Litharge** (PbO) is most generally used. **Sugar of lead**, incorporated in oil, is used for light tints. **Sulphate of zinc** and **manganese dioxide** are used by the grinder for certain paints having zinc white as a base. Cobalt driers are used where very rapid drying is essential.

Paints for Structural Steel. The priming coat of paint should be made of linseed oil containing thoroughly inhibitive or inert pigments such as basic chromate of lead, red lead, basic sulphates of lead, zinc oxide, iron oxide, zinc chromate, etc. A mixture of the lead, zinc, and iron pigments is sometimes preferred to the use of any single pigment.

The surface area of a steel structure may be calculated by use of the following formulas in connection with the material bills giving the tonnage of the various shapes.

Let S = sq ft of surface per ton of metal, and w = weight of shape per running foot, lb. Then, for

I beams: $S = (428h + 1720)/w$, where h = depth of beam, in.

Channels: $S = (434b + 500)/w$, where b = width of channel, in.

Angles (equal-leg): $S = (660b - 21)/w$, where b = width of each leg, in.

Angles (unequal-leg): $S = 3220b/w$, where b = sum of widths of both legs, in.

Z bars: $S = (528h + 1090)/w$, where h = depth of web (out to out), in.

Plates (both sides): $S = 100/t$, where t = thickness, in.

(75 percent) is generally used. Such coatings, if free from pinholes, are highly resistant to corrosion. The excellent "paint-holding" properties of terne plate fit it for many uses in building construction. Its "lubricating properties," in drawing and stamping processes, assist greatly in the manufacture of containers and fuel tanks.

Lead coatings on steel are most efficient in a polluted atmosphere as in industrial centers. In rural atmosphere, pinhole corrosion is soon evident. A "bonding" agent, either as an alloy in the lead or as an undercoat, is necessary for the process commonly used in applying lead coating, *i.e.*, the hot-dip process.

In coating or electroplating with **nickel or copper**, the object to be coated is made the cathode, the anode consisting of a block of the metal to be deposited, and the electrolyte, a solution of the metal to be deposited. In nickel plating, a copper coating is generally applied before the nickel to render the latter more adherent and more corrosion-resistant by making the entire coating more impervious. **Chromium** coatings which are now widely used are also produced by electroplating from chromic acid solutions. They are nearly always applied as a very thin finish on a nickel coating and are almost perfect in their tarnish resistance. Coatings of these three metals protect the underlying, or basis, metal from corrosion only in so far as they exclude air and moisture. Hence, the imperviousness of such coatings as determined by the conditions of deposition is of very great importance. Chromium plating on account of its great hardness is also used to some extent as a protection against wear and abrasion (see Blum, "Chromium Plating," *Mech. Eng.*, Jan., 1927, and "Mechanical Applications of Chromium Plating," *Mech. Eng.*, Dec., 1928).

Copper is sometimes applied in coats integral with the basis metal. Copper is cast around a steel billet which is afterward worked down to the required size. Most of the steel coated in this way is used for wire and gives a combination of high electrical conductivity and high tensile properties. It is also used for purposes requiring the combination of high corrosion resistance and strength as in concrete revetment mats used in river control. Steel clad with nickel or stainless steel is also available commercially.

Aluminum coatings cannot be made by electrodeposition in the ordinary way, although aluminum has been deposited from complex organic liquids in the form of coatings on steel. Aluminum coatings are usually produced by mechanical means. Such a coating has proved very useful on duralumin (p. 630), but on iron or steel its usefulness is limited by the brittleness of the intermediate alloy layer which generally forms.

Steel coated by immersion in molten aluminum (see below) resists atmospheric corrosion admirably. Its rough unattractive appearance restricts its use.

Calorizing is a process by which a coating of aluminum and aluminum-iron alloys is produced on iron and steel (brass, copper, or nickel may also be calorized) which protects the metal against high temperatures because of the formation of aluminum oxide on the surface. It does not protect against ordinary corrosion in the atmosphere or in liquids. Sulphurous acid and carbon monoxide have no appreciable effect on calorized metal. Bending or working of calorized metal should be done at a bright-red heat; threading must be done before calorizing, followed by chasing of the threads to make them fit smoothly without breaking the coating; dimensions and weights are increased by calorizing. Thermal and electrical conductivities are not appreciably changed. The base metal is soft annealed by the process. A

surface that is easily rubbed or washed. High-grade varnishes should be judged comparatively by their body, working properties, flowing, clearness, gloss, and durability. Practical exposure tests are best suited to determine the latter point. Hardness of film, resistance to scraping, elasticity when rolled with a knife blade, and resistance to moisture are some of the quicker tests used. Setting in from 4 to 8 hr and hardening in 24 hr are the limits sometimes specified. (See *Specifications of Federal Specifications Board.*) Varnishes which dry in 4 hr are made from tung oil and synthetic resins; they are very durable if of the long oil type. Gilsonite, elaterite, and other asphalts are melted into oils to form black lustrous asphalt varnishes that are used for protection of water tanks, piping, etc., with great success. Hard, flexible, clear, and rapid-drying insulating varnishes are used extensively for dipping and brushing commutator rings, transformer coils, and other electrical equipment. Baking varnishes for armature coils must be resistant to heat without blistering. (See *A.S.T.M. Specifications.*) Shellac (see p. 760) and other spirit varnishes, chlorinated diphenyl, and phenolic resins are used extensively for the above purposes.

Synthetic Resins. Phenolic compounds condensed with formaldehyde, as well as glycerin phthalate resins, are now widely used in the manufacture of quick-drying water-resisting varnishes. These and numerous other synthetic resins are also applied in the manufacture of spirit varnishes, lacquers, and other protective coatings. For a full discussion of the physical properties of such resinous materials, see the "Resin Index" in "Physical and Chemical Examination of Paints, Varnishes, Lacquers and Colors."

Ceramic Coatings. Metal fittings that are to be permanently protected are often coated and baked with a mixture of feldspar, borax, tin and lead oxides, and other similar materials. The enamel coating produced by this method is very resistant to corrosive agencies. It is, however, subject to cracking from expansion or contraction of the metal upon which it is placed.

Cement and Stucco Coatings. Cement and stucco are rough and hold dirt and soot. They may present water absorptive surfaces and may become spotted during rain storms. They may show surface fissures after weathering, under some conditions. Painting cement and stucco produces a smooth surface which will not hold dirt and will prevent rain spotting. If the cement is freshly formed, the free lime present is usually neutralized by applying a water solution of 3 lb of zinc sulphate per gal of water. After thorough drying, oil paints may be applied. If the cement or stucco surface is old and well weathered, this preliminary wash is not necessary. The priming coat of paint should consist of China wood oil varnish containing pigments. This dries hard and binds the surface particles, and prevents saponification. The second and third coats may be prepared cement paints or the regular type of linseed oil house paints. Emulsified pigmented glycerine-phthalate coatings are now being developed for this purpose.

Factory White. The interior walls and ceilings of factories are usually coated with gloss or flat mill whites made upon a titanium pigment lithopone-zinc oxide base. These paints are washable and sanitary and have a high coefficient of reflection. They are also used on interior surfaces of dwellings and public buildings. (See *U. S. Federal Specifications for Gloss and Flat Interior Whites.*)

Paint-destroying Agencies. Atmospheres containing sulphurous acid or ammoniacal gases are very severe in their action upon paint coatings. Sea air is also very destructive in its effect upon paint. Saline drippings from underground tunnels and fatty acids from machinery are also to be avoided. In dry climates and in communities of little industrial activity, paint coatings last for several years without decay.

Application. For painting large surfaces, the spray system of painting is now used. A paint spray gun operated by two men will usually cover as much surface in 1 day as could be covered by two men using hand brushes in 6 days. (See Reports on Spray Painting in "Papers on Paint and Varnish.")

spraying. It finds extensive application for automobile bodies and is known commercially as **Bonderizing** and **Granodizing**. Some of the phosphate treatments are electrolytically applied. The phosphate treatment is also applicable to zinc surfaces. The advantages of this latter process over the Bower-Barff and similar process are in greater cheapness and simplicity and the use of low temperatures.

Treatments somewhat analogous to the Parkerizing treatment are widely used for the treatment of magnesium alloys prior to the application of other types of coatings, such as aluminum-pigmented spar varnish and pyroxalin coatings of the duco type.

Protection of Aluminum Alloys. Wrought-aluminum alloys, especially of the duralumin type, are now largely used for aircraft purposes. Alloys containing copper as an essential alloy constituent, in sheet form, are susceptible to intercrystalline corrosive attack which results in the material becoming very brittle with little or no surface evidence of the change. Aluminum alloys containing magnesium or magnesium and silicon as the essential alloying constituents are very stable under prolonged weathering conditions. The protective coatings used on aluminum alloys depend on the severity of the service. A preliminary anodizing treatment to produce a film of oxide on the surface (formed by making the article the anode of a cell with chromic or sulphuric acid as the electrolyte) is now common practice. Such a surface oxide coating forms an excellent basis for the application of other coatings. Aluminum-pigmented spar varnish is excellent for this. For very severe marine conditions, the only coatings that give permanent protection are those of aluminum. Such a coating may be applied by the Schoop metal-spraying process and is especially useful for heavy pieces. A sheet product known as **Alclad** is now available commercially. This consists of a sheet of duralumin or other high-strength aluminum alloy coated with aluminum, the coating forming an integral part of the sheet. The aluminum is applied to the alloy billet, and the whole is rolled into sheet form. This product is not yet (1941) commercially available in tube form.

The passivating of iron surfaces may be accomplished in several ways, the most common consisting of immersion of the metal in nitric acid (sp gr 1.4) after it has been highly polished. Other methods consist in immersing the metal in fuming sulphuric acid, potassium ferrocyanide, or potassium chromate solution or in chromic acid; coating with a manganese dioxide paint; cathodic pickling in a weak acid solution, the metal being made the cathode in a circuit of low voltage; treatment with arsenic, sodium nitrite, etc. This condition of passivity is temporary, and, thus far, passivating has been of doubtful value, except for stainless steel for which it is a regular practice. A chromate treatment now used commercially on zinc surfaces is somewhat analogous to some of the above treatments.

The treatment of water with a bichromate, sodium silicate, or similar chemical to form a protective surface film on iron (steel) with which it comes in contact is common practice for such purposes as air conditioning in which the same volume of water must be used repeatedly over and over.

Slushing oils are usually non-drying oils or greases which remain soft for prolonged periods, are strongly adhesive on metals, but can readily be removed when desired. The best protection to metals is afforded by acid-free semisolid oils applied in a melted condition. Types of commercial slushing oils are petroleum residues, mixtures of lithopone and iron oxide with heavy petroleum residues, petrolatumlike compounds emulsified with chromate solutions, blown vegetable oils, soft asphalts thinned, rosin-base materials. A specification proposed several years ago is as follows: Coating shall

quality into "dense southern pine" and "sound southern pine"; dense southern pine should show on either end an average of at least six annual rings per inch and at least one-third summerwood, or else the greater number of rings should show at least one-third summerwood, all as measured over the third, fourth, and fifth inches on a radial line from the pitch; wide-ringed material excluded by this rule is acceptable, provided the amount of summerwood, as above measured, is at least one-half; the contrast in the color between summerwood and springwood should be sharp, and the summerwood should be dark in color, except in pieces having considerably above the minimum requirement for summerwood; sound southern pine includes pieces of southern pine without any ring or summerwood requirement); **Northern white pine** (wood from tree of that name grown in Maine, Michigan, Wisconsin, Minnesota, and Canada); **Norway pine** (Norway or red pine grown in Michigan, Minnesota, Wisconsin, and Canada); **Idaho white pine** (a species of white pine grown in Western Montana, Northern Idaho, and Eastern Washington); **Ponderosa pine** (timber known as white pine grown in Arizona, California, New Mexico, Colorado, Oregon, and Washington; sometimes known as Western yellow or ponderosa pine, or California white pine or Western white pine); **sugar pine** (white pine from California); **poplar** (wood from the tulip tree, otherwise known as whitewood, yellow poplar, and canary wood as well as aspen, cottonwood, and balsam poplar); **redwood, Eastern spruce** (spruce timber from points east of and including Minnesota and Canada, covering white, red, and black spruce); **Engelmann spruce** (spruce timber from the Pacific Coast); **sycamore; tamarack** (tamarack or eastern tamarack, grown in states east of and including Minnesota); **tupelo** (tupelo gum and bay poplar); **walnut** (black walnut).

Physical Properties

Weight and Specific Gravity. The weight of wood will vary with the amount of water contained, and (within a given species) with the age, part of tree from which the wood is cut, geographical location, etc. In general, green wood will contain 50 to 75 percent, air-dry wood 10 to 20 percent water. In general practice, a wood weighing less than 30 lb per cu ft is called light; one between 30 and 40 lb, medium; and one more than 40 lb, heavy. The approximate air-dry weight of any wood is from 10 to 20 percent higher than its absolute dry weight. For the **specific gravity** of various woods, see p. 687.

Hardness. According to Schenck ("Forest Utilization"), dense woods are the harder. Wide rings in oak and narrow rings in pine indicate superior hardness. Heartwood may be harder than sapwood, while dry wood is generally harder than green wood of the same kind.

Relative Hardness of Woods

Hard: Hickory, dogwood, sugar maple, sycamore, locust, hornbeam, persimmon.

Medium: Ash, oak, elm, beech, cherry, mulberry, birch, sour gum, longleaf pine.

Soft: Chestnut, tulip tree, sweet gum, Douglas fir, Southern pine, larch, basswood, horse chestnut, hemlock, cottonwood, spruce.

Very soft: White pine, sugar pine, redwood, willow.

A scale of hardness frequently used is as follows:

Scale of Side Hardness of Wood

(Based on Wood Handbook)

Dogwood	1.50	Ash (white)	0.95	Chestnut	0.41
Maple (hard)	1.09	Walnut (black)	0.76	Butternut	0.37
Oak (white)	1.00	Elm (American)	0.75	Poplar (yellow)	0.34
Birch (yellow)	1.00	Cherry (black)	0.72	Pine (eastern white)	0.30
Beech	0.98	Birch (paper)	0.68	Cedar (western red)	0.26
Oak (red)	0.98	Pine (longleaf)	0.65	Cedar (northern white)	0.24

PAINTS AND PROTECTIVE COATINGS

BY

HENRY A. GARDNER

REFERENCES: Gardner, "Physical and Chemical Examination of Paints, Varnishes, Lacquers, and Colors," Inst. Paint & Varn. Research. Circulars Nos. 1 to 610, Scientific Sec., National Pt. Varn. & Lacquer Assn. Reports of Committee D-1 of the *A.S.T.M.*, 1903–1940.

Preparation of Surfaces for Painting. If **new wood** is to be painted, it should be sandpapered lightly in rough spots. All knots should be coated with aluminum varnish just before applying the paint. Before applying a second coat, all nail holes and crevices should be stopped with putty. If the surface needs repainting, all "alligatoring," scaling, or blistering appearing on the old paint should be leveled with sandpaper. When **new metal** is to be painted, it should be cleaned of rust spots with a wire brush, scraper, or sandblast. Small articles are generally pickled in a hot 15 percent solution of sulphuric acid to remove the oxide scale from the surface, and then thoroughly washed and dried before painting. **Old painted steel surfaces** should be sandblasted, if in bad condition. Three coats of paint should be used on structural materials if good results are to be obtained.

Spreading Rates. The average spreading rate for a paint of normal consistency is as follows:

Spreading Rate for Paint in Sq Ft Per Gal

Coat	Wooden surfaces	Metal surfaces	Cement and concrete
Priming coat	300 to 400	500 to 700	150 to 250
Second and third coats	400 to 600	700 to 800	300 to 400

Cost of Painting. The cost of labor for painting any structure is generally four times the cost of the paint. The best paints from the standpoint of efficiency are those described below.

Pigments and Prepared Paints for Wooden Surfaces. The opaque white pigments used in paints for exterior surfaces are corroded **white lead** (basic carbonate), sublimed white lead (basic sulphate), **zinc white** (zinc oxide), titanium oxide pigments, and **leaded zincs** (lead sulphate combined with zinc oxide). Lead pigments used alone are apt to chalk and "alligator," while zinc pigments often scale and check. By combining the two types of pigments, these defects are minimized. Equal parts of lead or titanox and zinc form a good paint. Mixtures of lead and zinc pigments or lead, zinc, and titanium pigments are often combined with about 10 percent of the extender pigments such as **barytes** (barium sulphate), **china clay** (aluminum silicate), **silex** (silicon dioxide), **asbestine** (magnesium silicate), etc., to increase the durability of the product. Such combinations when finely ground by machine with pure linseed oil form excellent paints. They are tinted with **colored pigments** such as chrome yellow (lead chromate), Prussian blue (ferro-ferricyanide of iron), sienna, ocher, umber, and lampblack and sold as prepared paints. In combination with zinc oxide or white lead and zinc oxide, titanium pigments will give remarkable service on wood, metal or cement. (See *U. S. Federal Specifications for Exterior White Paints.*)

less costly plywood products. Plywood glues are usually mixed mechanically and spread by revolving spreaders. The assembled plywood must go under a hydraulic press (at approximately 75 lb per sq in. pressure) before the initial set of the glue has begun, and remain under pressure or in clamps for not less than 4 hr. It is then dried, cut to size, and sanded.

Decay and Destruction of Timber

Decay in timber is caused by fungi growing in the wood fiber and is favored by the presence of oxygen, water, heat, and food supply (see Boyce, "Forest Pathology," McGraw-Hill). Timber suffering from the forms of decay usually distinguished as dry rot, moist rot, wet rot, brown rot, etc., has little practical value. Decayed wood is lighter than sound wood, and loses its strength rapidly as the decay progresses.

Absolutely dry wood will not decay, nor will wood decay when constantly submerged in water, nor when kept more than 4 ft under ground. Poles and posts decay chiefly at the ground line. Construction timbers in buildings, bridges, etc., decay most rapidly at points where they come in contact either with other timbers, with the ground, or with stone or concrete walls. Any conditions favoring the retention of water in the timbers, particularly where the temperature is from 60 to 85 F, will bring about decay. Sapwood of all timbers decays very rapidly, heartwood is usually more resistant. In structural timbers, decay frequently appears in the inner sapwood, so as not to *be observable from the outside, even by the most careful inspection.* This form of decay is usually termed "internal sap rot." Where strength is the principal requirement, the most careful examination of timbers with large amounts of sapwood should be made, particularly if there is evidence that such timbers have been cut from the tree more than 2 or 3 months after felling. This applies particularly to all forms of piling, stringers, posts, caps, etc.

Blue stain is a grayish-blue discoloration found in the sapwoods of pines and other coniferous woods, due to a minute fungus (*Ceratostomella pilifera*) growing in the wood fiber. It has no effect on the strength of the wood, and may be prevented by dipping the freshly sawed lumber in a 5 percent solution of sodium carbonate kept at about 140 F.

Decay of Living Trees. Where decay, or dote, is found in the heartwood of timbers, it is usually due to disease of the living trees. Different forms of such decay are distinguished in conifers as red heart, dote, rot, and in hardwoods as piped rot, brown rot, speckled rot, etc. All these forms of decay cease after trees are felled, and *cannot be communicated to other pieces of sound structural timber.*

Weathering is the wearing away of the surface of timbers caused by exposure to the elements, and is of importance only with comparatively soft woods. Different forms are distinguished according to the color, as white, gray, or brown weathering.

Life of Woods. The natural length of life of wood and its resistance to decay vary with the kind of wood and the conditions under which it is used. In general, woods may be classed as long-lived, medium-lived, and short-lived, as indicated below.

Long-lived: Cypress, redwood, red cedar, white cedar, osage orange, catalpa.

Medium-lived: White oak, slippery elm, black walnut, hickory, longleaf pine, tamarack, Douglas fir.

Short-lived: Red oak, red gum, beech, elm, spruce, shortleaf pine, hemlock.

Destruction of Wood by Marine Animals. Piling and other timbers exposed to salt water in warm climates are destroyed by various species of marine wood borers, of which the principal forms are the teredo (known as the shipworm) and the limnoria (sometimes, through resemblance, called a wood louse). The teredo thrives in waters with a saline density above 1.0054, and at temperatures of from 55 F to the highest

One gallon of pure red-lead paint (20.3 lb red lead in 5.62 lb of linseed oil without turpentine or other thinner) when applied to new steel surfaces will cover from 500 to 700 sq ft for the first coat, 650 to 850 sq ft for the second coat, and from 800 to 1,000 sq ft for the third coat; or, for two-coat work, 1 gal will cover from 300 to 400 sq ft and for three-coat work from 215 to 285 sq ft. (Cloyd M. Chapman, *Eng. Rec.*, Feb. 15, 1913.)

Aluminum paint contains 1¾ to 2 lb of aluminum powder per gallon. In highly-diluted varnish liquids it withstands a temperature of 900 F. As a primer, on wood, it has high moisture-proofing efficiency, when covered with light tints of regular linseed oil paint. Suspended in spar varnish, aluminum powder increases greatly the moisture resisting power of the varnish. The low radiation loss makes aluminum paint valuable for furnaces and the high heat reflecting power reduces evaporation losses from oil storage tanks.

Zinc dust is an excellent protective of iron and steel surfaces. A so-called **liquid galvanizing** is made of zinc dust in boiled linseed oil. Mixed with 20 percent zinc oxide it makes a good primer for iron and steel and an exceptional primer on galvanized iron. Zinc dust is also effective when mixed with iron oxide and zinc oxide, in proportions zinc dust 50, iron oxide 30, zinc oxide 20 percent. As zinc dust retards drying some additional drier may be used under adverse drying conditions. Zinc dust may be added to gray topside paints for vessels to increase resistance to corrosion.

Carbon Paints. Paints containing graphite, carbon black, or lampblack are unsafe to use as a priming coat for metal. Because of their electrical conductivity, they are apt to excite corrosion. Their use as second-coaters or top-coaters is to be recommended.

Ship-bottom Paints. Anticorrosive priming paints made of the rust-inhibitive pigments noted above and topped with quick-drying antifouling paints made of shellac dissolved in alcohol or resin-coal tar solutions and mixed with powdered zinc and the oxides of zinc, iron, and mercury are widely used in the Navy and merchant marine service for the protection of steel vessels. Some synthetic resin paints with light-colored pigments also give good results. Barnacles are phototropic and do not go to light-colored surfaces.

Paints for Water Carriers. Cast-iron and riveted-steel water carriers are generally heated and dipped in hot preparations of mineral asphalt, coal tar, and lime, or special baking enamels. This treatment is occasionally followed by baking at a high temperature to make the coating more resistant to abrasion. Recently certain types of synthetic resins have been found to be very effective.

Paints for Tinned and Galvanized Surfaces. After wiping off the greasy surface with benzine, a linseed-oil paint made of red lead, iron oxide, and chromate pigments, thinned with a little varnish, gives good results on tin. For galvanized iron use zinc-dust primers. Applying a 5 percent water solution of copper nitrate and sal ammoniac or a phosphoric acid compound to galvanized iron previous to painting is also recommended.

Rubber Paints. Paints made of caoutchouc, gutta percha, chlorinated rubber, etc., dissolved in coal-tar distillates form elastic films which give some protection to metal. Upon weathering, the films soon show pinholing and brittleness if ordinary rubber is used.

Metal Lacquers. Cellulose nitrate dissolved in butyl acetate and other solvents and thinners are widely used in coating automobiles and other manufactured metal objects. They are usually pigmented. They are generally applied by spraying. They dry with great rapidity and produce highly durable films. Phenolic and glycerine phthalate resins are usually present in such lacquers.

Varnishes. Gums melted into oils and thinned with turpentine form oleoresinous varnishes. For exterior purposes, a "long" oil varnish (one that contains a high percentage of oil) is superior. For interior use, a "short" oil varnish gives a highly lustrous

tive. In one run of a thousand ties treated with creosote, where all the ties were exactly the same size, the average absorption was 23 lb of creosote, but some of the pieces absorbed as low as 2 lb and some as high as 90 lb.

Whenever possible, only thoroughly air-seasoned timber should be treated, because wood containing appreciable amounts of water will not absorb creosote. Steaming of green timber reduces its strength (see Hatt, "On the Effect of Steaming on Wood," *Proc. A.R.E.A.*, 28, 1927, p. 1164). Whenever possible, all injuries to wood after treatment should be avoided. All framing, boring, and adzing should be done before treatment.

The principal preservatives used, mentioned in the order of quantities used in 1939, are: coal-tar creosote (creosote oil), coal-tar creosote solution, creosote-petroleum mixture, chromated zinc chloride, and zinc chloride. Small quantities of mercuric chloride were used. In addition to the above, petroleum oils and petroleum residues were used mixed with creosote. Of these preservatives, the order of efficiency is as follows: coal-tar creosote and creosote coal-tar solution, mercuric chloride, and zinc chloride. Water-gas tars have some antiseptic value but are probably not equal to coal-tar creosote. Petroleum has no antiseptic value, but is added to creosote to reduce checking. In addition to the above, there are numerous proprietary preservatives whose value is frequently not commensurate with the cost. A number of new preservatives have developed whose ultimate value has however not yet been demonstrated.

Description and Specifications for Preservatives

(For standard specifications see *Manual A.R.E.A.; Manual A.W.P.A.;* For methods of analysis see also *A.S.T.M. Standards*)

Creosote. Coal tar yields on distillation from 30 to 50 percent of creosote. It is not a simple substance but contains a large number of chemical constituents. Creosote specifications confine themselves to the requirement that the creosote must be a direct product of coal-tar distillation, free from adulteration, with limited material insoluble in benzol, and that certain definite percentages distil at standard temperatures.

At 65 F, creosote weighs about 8.7 lb per gal; at 100 F (the standard temperature) the specific gravity ranges from 1.03 to 1.12. It has high antiseptic properties and is practically insoluble in water. There are three grades of coal-tar creosote recognized in the trade which are distinguished chiefly by their specific gravities and percentages of low and high boiling compounds. The heavier oils are considered the more valuable. **Creosote coal-tar solution,** is a solution of coal-tar in creosote in varying proportions (20 to 40 percent coal tar). **Creosote-petroleum mixture** is a mixture of creosote and petroleum.

Water-gas tar distillate is obtained from water-gas tar by distillation. **Water-gas tar solution** is a solution of water-gas tar in water-gas tar distillate (not more than 40 percent water-gas tar).

Chromated zinc chloride is a mixture of approximately 80 percent zinc chloride and 20 percent sodium dichromate.

Zinc chloride is soluble in water and tends to leach out of timber in wet locations or in regions of heavy rainfall. Combinations of zinc chloride with creosote and of zinc chloride and water-gas tar and water-gas-tar solution are in use (see Card process, p. 683).

Processes of Treatment

(For detailed recommendations and Standard specifications, see *Proc. A.R.E.A.*, 1939; *Manual A.R.E.A.; Manual A.W.P.A.*)

Bethel or Full Cell Process. After a preliminary vacuum, creosote is injected under pressure varying from 40 to 200 lb per sq in., which is continued until the desired absorption has been obtained. The amount of creosote injected will vary from 10 to 25 lb per cu ft. This process is used largely for the treatment of piling, bridge materials, paving blocks, telegraph poles, and other timbers from which a long service is expected and where mechanical or destructive processes, aside from decay, are of minor importance. In general, bridge materials, piling, poles, and similar timbers are treated with about 16 lb of creosote per cu ft. For marine piling 22 lb or refusal treatment should be used.

WOOD

BY

HERMANN VON SCHRENK

(Revised by C. C. Forsaith)

References: Bulletins and Circulars of the U. S. Forest Service. "Wood Handbook," U. S. Dept. Agr. "Guide to the Grading of Structural Timbers and the Determination of Working Stresses," *U. S. Dept. Agr. Misc. Pub.* 18. Also *U. S. Dept. Agr. Tech. Bull.* 158 and 479. Weiss, "Preservation of Structural Timbers," McGraw-Hill. Record, "Identification of the Economic Woods of the United States," Wiley. Brown and Panshin, "Identification of the Commercial Timbers of the United States," McGraw-Hill. Koehler and Thelen, "Kiln Drying of Lumber," McGraw-Hill.

Definitions and Classification. Timbers are classed commercially as hardwoods and softwoods. Typical **hardwoods** are oak, ash, chestnut, hickory, maple, and poplar; typical **softwoods** are pines, hemlock, spruce, larch, fir, and cedar. The terms "hard" and "soft" do not necessarily refer to actual hardness (see table, p. 678). In all timbers, two forms are distinguished, heart and sapwood. **Heartwood** is the inner part of a tree, usually darker in color than **sapwood** (the outer part), frequently heavier, and more decay-resistant. Knots or branch inclusions (loose or solid) are defined as **pin knots** (not over ½ in. diam), **standard knots** (not over 1½ in.) **large knots** (more than 1½ in.), **sound knots** (solidly grown together with the surrounding wood), **loose knots** (not held firmly in place by growth or position), **pith knots** (sound knots with pith holes not more than ¼ in. in diam), **encased knots** (*i.e.*, entirely surrounded by bark or pith), **rotten** (decayed) **knots**, **spike knots** (knots sawed lengthwise). Recognized **defects** are **wane**, bark or the lack of wood from any cause on the edge; **shakes**, splits or checks in timber, which usually cause a separation of the wood between annual rings; **sap stain**, a discoloration of the sapwood; **pitch pockets**, openings between the grain of the wood, containing more or less pitch; **dote** and **red heart**, various forms of decay.

Timbers are sold under various names. The following list of **standard commercial names of timbers** has been adopted by the N.B.S. (Simplified Practice Recommendation, No. 16, July 1, 1926 and R16-39) and in part by the A.R.E.A. (Vol. 27, 1926, p. 833) and the A.S.T.M. (1927 Standards, Pt. II, p. 700). The species included in each name are given in parentheses.

Ash (white, black, blue, green, and red ash); **basswood** (linden, linn, lind or lime tree); **beech** (red and white beech); **birch** (paper, white, yellow, and black); **buckeye** (wood from the same genus as the horse-chestnut tree); **butternut** (butternut also known as white walnut); **cherry** (sweet, sour, red, wild, and especially the black cherry); **chestnut**; **cottonwood**; **cypress** [red, (coast type); yellow (inland type); white (inland type)]; **elm, soft** (American or white, red or slippery elm); **elm, rock** (rock or cork elm); **Douglas fir** [(coast type); red, (intermountain type); red (Rocky Mountain type)]; **gum** (red gum, black gum); **sweet gum or satin walnut**; **Eastern hemlock** (from all states east of and including Minnesota); **West Coast hemlock** (hemlock from the Pacific Coast); **hickory** (shell-bark, kingnut, mockernut, pignut, black, shagbark, and bitternut); **Western larch** (larch or tamarack from the Rocky Mountain and Pacific Coast regions); **maple, soft** (soft and white maple); **maple, hard** (hard, rock, and sugar maple); **white oak** (white, burr or mossy cup, rock, post or iron, overcup, swamp, post, live, chestnut or tan bark, yellow, and basket or cow oak); **red oak** (red, pin, black, water, willow, Spanish, scarlet, Turkey, black jack or barn, and shingle or laurel oak); **pecan**; **Southern pine** (all pines of the Southern states manufactured into lumber, including longleaf, shortleaf, loblolly, and Cuban pines. The lumber is divided according to

both sides, S-1-S or S-2-S, is $\frac{25}{32}$ in. thick. A standard **industrial board,** surfaced smooth on one or both sides, S-1-S or S-2-S, is $\frac{25}{32}$ in. thick. For details as to sizes, measurements, shipping provisions, tally, grade marking, etc., see above references.

Structural timbers are **graded,** by inspection, as follows: **Select** (S2) grade is especially adapted to heavy construction, such as railway, bridge, and mill work. **Standard** (S3) grade is primarily suitable for general building use and common mill construction. **Common** (S4) grade is especially recommended for small house construction where stiffness is a controlling factor and where strength requirements are not so critical. These three grades furnish the greater portion of the structural timbers used. **Extra Select** (S1) grade is an exceptional grade intended to meet the most exacting strength requirements for construction purposes. The grades are based on the density of the wood and on the defects present. Density is determined by observing the spacing of the annual rings and the percentage of summer wood. Permissible defects, such as knots, checks, shakes, and cross grain, vary with the proposed use of the structural member and with the location of the defects in that member (see also *Manual A.R.E.A.*)

Structural materials are also graded according to the use to which they are to be put, *i.e.*, joist and plank, beams and stringers, posts and timbers.

Shipping Weights. The weights of lumber are given either as green, shipping weight (air dry), or kiln dried. The average weight will vary materially, depending upon the item of lumber, such as sheathing, flooring, timbers, etc.

Table 1. Estimated Shipping Weights of Lumber
Lb per 1000 Ft B. M.
(Based on rough 1 in.)

Shingles. Pine shingles are usually 16 in. long, $2\frac{1}{2}$ to 14 in. wide, $\frac{1}{16}$ in. thick at the small end, and $\frac{5}{16}$ in. thick at the butt end. A standard shingle

Cleavability is inversely as the resistance to splitting in a lengthwise direction. According to Schenck ("Forest Utilization"), cleavability is affected by: (a) the straightness, length, and elasticity of the fiber; (b) the heaviness of the wood rays; (c) straightness of growth; (d) branchiness; (e) moisture (the higher the moisture the easier the wood can be split); (f) frost (reduces cleavability); (g) hardness.

Relative Cleavability of Woods

Hard to split: Black gum, elm, sycamore, dogwood, beech, holly, maple, birch, hornbeam.
Medium: Oak, ash, larch, cottonwood, linden, yellow poplar, hickory.
Easy to split: Chestnut, pines, spruce, fir, cedar.

Heat Value. The specific heat of practically all kinds of wood when oven-dry is 0.327 (Dunlap, *Forest Service Bull.* 110, 1912). The heat value of wood depends on its specific gravity (oven-dry), heavier woods giving more heat than light woods. According to Schenck, 1 cord of green wood may contain 250 gal of water (dependent upon the species, density of the wood, degree of dryness, etc.), and the heat required to evaporate this into steam is not available for other heating purposes. According to German experiments, wood with 45 percent moisture gives only 50 percent as much heat as oven-dry wood. Resin increases the heating power by about 12 percent. According to Roth, 100 lb of wood, as sold in wood yards, contains 25 lb of water, 74 lb of (oven-dry) wood, and 1 lb of ashes. Thus, 100 lb of green wood (50 percent moisture) furnish about 270,000 Btu, 100 lb of air-dry wood (10 percent moisture) about 580,000 Btu, and 100 lb of kiln-dry wood about 630,000 Btu.

Relative Values of Woods as Fuels

Best: Hickory, beech, hornbeam, locust, heart pine.
Good: Oak, ash, birch, maple.
Moderate: Spruce, fir, chestnut, hemlock, sap pine.
Poor: White pine, alder, linden, cottonwood.

Strength of Woods. See p. 687.

Plywood

Plywood is laminated or compound wood and consists of several sheets (plies or folds) of thin wood (or veneer) glued together, either in flat or curved shapes. Usually, the adjacent layers or sheets of wood have their respective fibers or grain at right angles to each other. Internal stresses and strains are balanced in such construction, resulting in permanence of dimension and shape.

The veneer used in assembling into plywood is manufactured in four ways: (1) Rotary cut from logs revolved in a veneer lathe; about 92 percent of all veneers are made in this manner. (2) Slice cut from the flat surface of logs or flitches moved angularly against a slicing knife. (3) Sawed on a segment saw; not economical on account of the saw-kerf waste. (4) Half-round cut from flitches mounted on a wide-swing or eccentric lathe.

The straightening out or flattening of rotary-cut veneer results in checks on the concave side. In veneer $\frac{1}{16}$ in. thick and less, these cutting checks are negligible, but in veneer $\frac{1}{8}$ and $\frac{3}{16}$ in. thick their presence affects the strength.

The glues used in plywood (see p. 697) include the following: Animal glue penetrates wood well, and is best applied in a hot room; it is soluble in water. Vegetable glue is economical in cost, principally used for plywood, of abundant strength, easy to use, but not waterproof. Casein glue is practically non-soluble in water and is usually specified for plywood for vessels, aircraft, and other exposed locations. Albumen glue when properly coagulated is practically waterproof, and its use is permitted under the most rigid waterproof specifications. Silicate glue is a low-priced glue used in box shooks and

Bark is usually sold and bought by the cord. The tanneries, however, apply the name to a weight of 2,240 lb, instead of to 128 cu ft. Twelve cords of bark fill one common (old) freight car. A stack of bark contains 30 to 40 percent solid bark. The specific gravity of fresh oak bark is 0.874; dried, it is 0.764. The bark of white oak varies from 55 percent of the wood in trees 20 years old to 21 percent in trees 140 years old. The average bark yield of chestnut oaks per tree (in cords) is as follows: trees 6 in. in diam, 0.013; 12 in. trees, 0.073; 18 in. trees, 0.195; 24 in. trees, 0.375.

Table 3. Number of Cubic Feet of Solid Wood per Cord, with Corresponding Diameters of the Average 4 ft Stick
(From U. S. Forest Service Bulletin 96)

STRENGTH OF WOOD

By LIONEL S. MARKS

(For references, see p. 877)

The strength of wood-substance must be distinguished from the strength of large timbers containing defects such as knots and crooked grain. Wood-substance exhibits an elastic limit under usual rates of test loading; under continuous loads it is markedly plastic and the modulus of elasticity may be only half as great as listed in the tables. Under impact, the elastic limit is frequently twice as great as listed in the tables. Strength is also affected by temperature, and very greatly affected by moisture. Table 1 represents results of a series of timber tests of the Forest Service on representative trees collected from the forest. Inasmuch as the strength of species is affected very greatly by the age of the tree, site conditions, and the inherent variability of individuals, strength values of wood cannot be quoted with any exactness.

Relation of Physical Properties to Specific Gravity. As a rule, strength varies directly with the dry specific gravity. An approximate value S of various strength functions is given by the equation $S = mg^n$, where g is

found along our coasts. It lives in clear and turbid water but cannot live in waters with high sewage contamination, and seldom to a depth below 30 ft. It works most rapidly in warm water. Unprotected pine piles will be destroyed in approximately the following times at various points: Norfolk, Va., 1 to 5 years; Pensacola, Fla., 1 to 3 years; Galveston, Tex., 5 months to 1½ years; Colon, Panama, 9 months to 1 year; Puget Sound points, 1 year; Klawak, Alaska, 1½ to 3 years. The limnoria requires pure salt water and cannot live in dirty water. It occurs sparingly in Long Island Sound, is quite abundant along the coast of Massachusetts, and does great damage along the Gulf of Mexico and along the North Pacific Coast. All untreated woods grown in the United States used for piling are subject to the attack of marine borers. A number of tropical woods are immune. For preventive measures, see Creosoting, p. 682. For description, see *U. S. Forest Service Circular* 128, "Preservation of Piling against Marine Borers"; report on the San Francisco Bay Marine Piling Survey (*Proc. Am. Preservers, Assn.*, 1921, 1922, 1923, and 1927); report of National Research Council Marine Piling Committee, "Marine Structures, Their Deterioration and Preservation" by Atwood and Johnson, 1924, with bibliography.

Destruction of Wood by Insects. Termites, or white ants, destroy untreated wood. They live in the ground and enter buildings and structures only from the ground. The mature insects, or "flying ants," are harmless. The workers can dissolve lime mortar; hence only cement mortar should be used for foundations. Their entrance into buildings can best be prevented by absolutely sealing the foundation walls, both sides and top, with rich cement mixture and coal-tar pitch. Joints between concrete beams or floors should have a coal-tar pitch seal. All wood, except creosoted wood, should be kept away from ground connection. Creosoted wood is immune. In the tropics, several species of ants attack wood aboveground (such as telegraph and telephone poles, cross arms, etc.); the use of creosoted wood is recommended in such regions (see Snyder, *U. S. Dept. Agr., Bull.* 94, *Pt.* II, 1915).

Timber Preservation

Seasoning of Timber. Timber can be seasoned either by air drying or by artificial means. In **air drying**, excessive splitting may be prevented either by painting the exposed ends of logs, timbers, or planks with common paint or preferably with coal-tar creosote, or by driving in sharp-edged irons of wedge section, shaped in the form of the letter S, and usually called S irons. The base of the wedge section should be ⅛ in. thick. **Artificial drying** is usually done in kilns (see Tiemann, "The Kiln Drying of Lumber"). Coniferous woods can be dried more rapidly than hardwoods and at higher temperatures, without affecting their strength. The latter should be dried very slowly. Small pieces of wood can be dried so as to prevent checking by soaking them from 1 to 7 days in a concentrated salt solution. The soaked pieces should then be piled in the air to dry. Another plan for drying small pieces is to pile them in bone charcoal.

Timber Preservation. The prevention of decay due to fungi and the protection of timber against wood borers are accomplished by the injection of various chemicals. The principal requirements for successful chemical preservation are: as thorough impregnation of the wood as can be obtained; the injection of sufficiently large quantities of the preservative; the injection of efficient chemicals; and the use of thoroughly sound and seasoned wood.

The **penetration** obtained will vary with the preservative. Water solutions, such as zinc chloride, will usually penetrate clear through a stick. Coal-tar creosote will penetrate sapwood only in coniferous woods (the heartwood of pines is slightly penetrable in large pieces, wholly so in small pieces like paving blocks), and in many hardwoods such as gum, white oak, hickory, and ash. It will penetrate into the heartwood of red oak, elm, and sycamore, and into the heartwood of small pieces of pine, spruce, etc., such as paving blocks. Individual pieces of timber absorb different quantities of preserva-

the specific gravity of oven-dry wood and m and n have values which vary with the condition of the wood and the kind of stress to which it is subjected. Thus for small clear specimens, the modulus of rupture is obtained by putting $m = 25{,}530$, and $n = 1.20$; when the wood is green, $m = 19{,}140$ and $n = 1.27$; for green longleaf pine, $m = 20{,}800$ and $n = 1.5$. (Betts, International Engineering Congress, 1915.) See also Fig. 1. The value of n varies with the strength function under consideration and ranges from unity for compression parallel to the grain to 3 for ultimate rupture work. For shearing stress, n is approximately unity.

The density and strength of *summer wood* of the pines are about twice as great as in the *spring wood*. The proportion of summer wood gives an excellent indication of strength.

Moisture Content, Shrinkage, Specific Gravity. The percentage of moisture in wood is based upon the oven-dry weight of the wood. Thus wood which weighs 35 lb per cu ft when oven-dry and contains 50 percent moisture when green will then weigh 35 plus 17½, or 52½ lb per cu ft. In large beams, the cubic foot reckoned is not the shrunk cubic foot when oven-dry, but the cubic foot of volume occupied by the wood at the time of the test.

The **specific gravity** as based on oven-dry volume may be obtained from the specific gravity as based on green volume by allowing for shrinkage.

The **volumetric shrinkage** of wood from the green to the oven-dry state, expressed in percentage of volume, is approximately 26.5 times the specific gravity as based on green volume. Thus, for white oak, shrinkage $= 0.60 \times 26.5 = 15.9$ percent, and consists almost entirely of lateral contraction.

The specific gravity of **wood-substance**, of which 50 to 60 percent is **cellulose**, is very nearly **1.5**. A solid cubic foot of wood-substance would weigh nearly 93.6 lb.

Toughness and Strength. The order of technological values of various woods does not coincide with that indicated by the strength values. Toughness and strength combined indicate this value, which is shown by the work U_R required to break a beam. Values of U_R (in.-lb per cu in.) are given in Table 1; for hickories and rock elm U_R varies from 24 to 40; ashes and elms, 14 to 24; oaks, black spruce and maple, 8 to 14; white spruce, firs, and other pines, below 8. This factor U_R does not vary directly with specific gravity. For instance, eucalyptus, a strong and heavy wood, is comparatively brittle and ranks low in rupture work.

Tensile Strength. The tensile strength of wood parallel to the fibers (or grain) exceeds all other strength values. At 15 percent moisture, values of tensile strength (pounds per square inch) according to Johnson, are: elm, 29,000; hickory, 32,000; larch, 19,000; longleaf pine, 17,300. Bovey gives 11,612 for Douglas fir, and Isaacs, 15,900. Tensile strength parallel to fiber is not important, for other stresses, as shear, or tension perpendicular to fiber, bending, or bearing, govern design. **Tensile strength perpendicular to the fibers** may be taken at 900 lb per sq in. for hardwoods and 250 lb per sq in. for conifers.

Shearing Strength. The shearing strength parallel to the fibers of small, clear, green specimens may be taken as approximately 1,100 lb per sq in. for hard woods and 600 lb per sq in. for conifers except the following: cypress, Douglas fir, red pine, tamarack, 800; and longleaf pine, 1,000. The values are increased from 50 to 100 percent by careful seasoning. For **shear in flexure**, see Table 2.

The Lowry process aims to secure a good penetration with comparatively small quantities of creosote. Air-dry timber only is treated. Creosote oil is forced into the timber without a preliminary vacuum until a large quantity of creosote is absorbed, usually stated as "treatment to a refusal." A quick final vacuum is then applied and a considerable amount of the injected oil is withdrawn. In standard railway-tie treatment, about 2½ gal of creosote remain in a 6 in. × 8 in. × 8 ft tie and relatively more for larger sizes.

The Rüping process is intended to secure a good penetration with comparatively small quantities of oil. Compressed air is first forced into the wood up to a pressure of 75 lb per sq in., after which creosote oil is forced in at a higher pressure until treatment to a refusal is obtained. A final vacuum aids the compressed air in driving out a considerable quantity of the injected oil. In standard practice, 1.8 to 2 gal are left in a 6 in. × 8 in. × 8 ft railway tie.

The boiling process is used chiefly for Douglas fir. The green timber is placed in the creosoting cylinder, which is then filled with creosote and heated under vacuum to a point slightly above the boiling point of water. This heating is maintained until practically no water comes out of the condenser. Pressure is then applied and the preservative is forced into the timber to the requisite amount.

In the **Card process**, the preserving liquid is made up of 15 to 20 percent of creosote or water-gas distillate or water-gas-tar solution and the remainder of a 3 to 5 percent solution of zinc chloride. The creosote and zinc chloride are mixed in a centrifugal pump, and the emulsion thus produced is forced into the timber under pressure.

The open-tank treatment includes a number of methods for treating timber, without pressure, with either zinc chloride or creosote. The timber is put in an open tank and heated in hot liquid for several hours. It is then quickly immersed in cold liquid. During the cooling process, a partial vacuum is produced in the wood and the preservative enters under atmospheric pressure. This process is adapted particularly to the treatment of small quantities of timber in localities where larger treating plants are not available (for details, see *U. S. Forest Service Circulars* 101, 104, 111, and 117).

The length of life obtained from treatment will vary with the preservative used, the kind of material treated, the type of use and the region in which used. According to the A.R.E.A. reports (vol. 20, p. 150, 1919), cross tie streated with zinc chloride may be expected to give double the length of life of untreated timber, regardless of where used. Creosoted ties may be expected to give 25 years or more service depending upon the kind of wood, the amount of mechanical protection given, and the traffic. Piling when treated with sufficient creosote will give 15 years or more. Bridge timbers treated with sufficient creosote will give 25 years or more. In all cases, the higher the initial retention of creosote per cubic foot, the greater the probability of long life.

Standard Grades and Sizes of Lumber

By agreement of lumber manufacturers, users, and the U. S. Forest Service, and under the auspices of the U. S. Department of Commerce, all softwood lumber products have been standardized as to grades, sizes, and nomenclature. This agreement is known as the **American Lumber Standards.** (For details, see Revised Simplified Practice Recommendation, No. 16, July 1, 1926, U. S. Dept. of Commerce. See also *Manual A.R.E.A.*, and *A.S.T.M. Standards*, 1939, Pt. II, pp. 494–512.) Lumber is classified into: **yard lumber** (less than 5 in. in thickness) for general building purposes; **structural timbers** (over 5 in. in thickness) for structural purposes; and **factory or shop lumber** intended to be cut up for use in further manufacture.

Yard lumber is classified into grades, either select (good appearance and finishing), or common (containing defects but of general utility). Select grades may be grades A to D depending on defects and use for certain purposes. Common grades may be grades 1 to 5 depending on defects and use for specific purposes.

The unit of lumber measurement is the board foot, a piece 12 × 12 × 1 in. A **standard** commercially-dry **yard board,** surfaced smooth on one or

tension face of a beam seriously influence its strength. Knots greater than 1½ in. diam diminish compression strength from 15 to 20 percent. They do not influence stiffness or the elastic limit of beams. For beams the range of stress between the elastic limit and modulus of rupture is seriously influenced by knots, crooked grain, and other defects. Checks and shakes both in green and seasoned timber bring about failure of beams by splitting at the ends under horizontal shear. When failure by shear occurs, however, the modulus of rupture is approximately equal to that of beams failing otherwise.

Tests of **large sizes in compression** show the following general ranges of ultimate strength (Lanza): white pine and spruce, 2,000 to 3,000; yellow pine, 3,500 to 5,500; white oak, 3,000 to 5,000.

References: Talbot, *Eng. Exp. Sta., Univ. Ill. Bull.* 41; McFarland, *Bull. Am. Ry. Eng. Assn.*, vol. 14, No. 149, Sept., 1912. For complete list of full-sized tests, see *Trans. Am. Ry. Eng. Assn.*, vol. 10, Part I, 1909.

Strength as Affected by Moisture Content. A comparison of the results of tests on air-seasoned material with those on green material shows that, in general, all the **mechanical properties** are **improved by seasoning.** Increase in strength is especially marked on small pieces free from defects. Increase in strength of wood fiber due to drying is, in the case of large timbers, largely offset by a weakening of the timber due to the formation of checks. If the moisture content of a seasoned timber is increased, it loses strength rapidly, and if thoroughly soaked with water will become slightly weaker than when green. On this account, it is not safe in practice to depend upon an increase in strength in timbers due to seasoning. When, however, large beams are seasoned with ordinary care, it is safe to assume that they will not at any time be weaker than they were when green.

Table 3. Relation of Moisture Content to Compressive Strength

(From Circular 108, U. S. Forest Service Compression parallel to grain)

Percentage of moisture in the wood	Relative maximum crushing strength compared to that of wood containing 2 percent of moisture		
	Red spruce	Longleaf pine	Douglas fir
2	1.000	1.000	1.000
4	0.926	0.894	0.929

(a) Green. (b) Air-dry.
(c) Kiln-dry (approx).

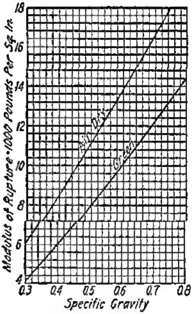

Fig. 1.—Modulus of Rupture of Wood.

is 4 in. wide. Cypress shingles are 16 in. long, and 5 butts measure 2 in. in thickness. A thousand shingles (4 to 5 bundles) will cover 100 to 150 sq ft of roof, according as laid from 4 to 6 in. to the weather. Shingles are usually laid to show 4 in. of their length, forming with 16 in. shingles a quadruple layer on a roof. The higher the grade of the shingles, the larger the weather face permissible. Cypress shingles are the most durable, followed by redwood, cedar, pine, and spruce (poor). Redwood shingles are the least inflammable. The weight of shingles (pounds per 1,000 shingles) is approximately as follows: cypress, 300; western white pine, 250; Washington cedar, 160 to 220; redwood (6 × 16 in., per bundle of 147), 42.5.

Cordwood. Firewood, pulpwood, and other small pieces of wood are usually bought and sold by the cord. A cord is equal to 128 cu ft of stacked wood. The standard cord is a stack of wood cut into 4 ft lengths, *i.e.*, 4 ft high and 8 ft long. A cord foot is one-eighth of a cord. The expression "surface feet" means the number of square feet measured on the side of the stack. In countries using the metric system, wood is piled in cubic meters (1 cu m = 0.274 cord). The actual volume of solid wood in a cord will depend, among other factors, on the form and size of the sticks, the amount of bark, whether split, and on the method of stacking (see Table 3). Ordinary conifers produce a greater amount of wood per cord than hardwoods, because of the smoother, straighter sticks. One cord of first-class split wood obtained from sound pieces 12 in. diam contains 102.4 cu ft of solid wood. Composed of inferior pieces having a diam of 6 in., a cord contains 97 cu ft of solid wood. While no absolute ratio can be given of the relation between cord measure and board measure, a fair average is 6 board-feet to each cubic foot.

Table 2. Contents in Feet (B. M.) of Joists, Scantlings, and Timbers

The relation between the specific gravity (dry) and the modulus of rupture of both air-dry and green wood as determined by the U. S. Forest Service is shown in Fig. 1. (Newlin, *Am. Lumberman*, Jan. 16, 1915.)

Determination of Working Stresses

(From *U. S. Dept. Agr. Misc. Pub.* 185)

Basic Stresses

The values listed in Table 4 afford a basis for the computation of design stresses. They are basic stresses for clear material used under such conditions of exposure that deterioration is not to be expected—*e.g.*, timbers that remain too dry to support the growth of decay. Except for stress in compression perpendicular to grain, they also apply to timbers that will remain too wet for decay to attack them. They are applicable to long-time loading and require modification (1) for the grade of timber used and (2) for the conditions of exposure to which it will be subjected in service. With certain exceptions, multiplication of the values in Table 4 by the strength ratio corresponding to the grade gives the design stress for material that will remain either dry or saturated.

Higher initial strength than would otherwise be required is desirable in timbers exposed to decay or other deterioration in order to offset the effects of deterioration. It may be provided by arbitrarily increasing the size of the timbers or by using lower design stresses. Table 5 includes values for three types of exposures.

Table 5. Average Ratios among Stresses for Different Exposures

Kind of stress	Type of exposure, percent		
	Continuously dry or continuously submerged	Occasionally wet but quickly dried	More or less continuously damp or wet
Stress in extreme fiber in bending	100	85	71
Stress in compression perpendicular to grain	100	70	58
Stress in compression parallel to grain	100	92	78
Stress in horizontal shear	100	100	100
Modulus of elasticity	100	100	100

The "occasionally wet but quickly dried" classification applies to timbers in outside locations but not in contact with the soil as in open-deck structures of railway trestles. In such instances, the material is subjected to wet or moist conditions at intervals but may be expected to dry quickly enough so that the decay hazard is only moderate. The "more or less continuously damp or wet" classification covers material, such as piling, sills, or dock timbers, where wet and drier conditions alternate, with the drying taking place slowly so that the average moisture condition is more favorable to decay.

No simple rule for modifying design stresses can cover all conditions of use. Factors to be considered include the extent to which the exposure favors decay, the expected life of the structure, the frequency and thoroughness of inspection, the original cost and cost of replacements, and the amount of sapwood permitted. If treated timbers are used, the efficiency of the treat-

Table 1. Strength of Small Specimens of Green and Air-seasoned Timber

(Average physical and mechanical properties, based on tests of small clear specimens 2 × 2 in. in cross section; bending span, 28 in. Mainly from Circular No. 213, U. S. Forest Service)

Species, common name	Moisture content, percent	Specific gravity based on volume when tested	Shrinkage in volume from green to oven-dry condition, percent	Static bending: Fiber stress at elastic limit, lb per sq in.	Static bending: Modulus of rupture, lb per sq in.	Static bending: Modulus of elasticity, 1,000 lb per sq in.	Static bending: Work to max load, in.-lb per cu in., U_R	Compression parallel to grain: Crushing strength, lb per sq in.	Compression perpendicular to grain: Stress at elastic limit, lb per sq in.	Hardness—load required to imbed a 0.444-in. ball to one-half its diam: End, lb	Hardness—load required to imbed a 0.444-in. ball to one-half its diam: Side, lb	Shearing strength, parallel to grain, lb per sq in.

MISCELLANEOUS NON-METALLIC MATERIALS

BY

E. C. CROCKER

(With the Assistance of Various Members of the Staff of Arthur D. Little Inc.)

ABRASIVES

REFERENCES: "Abrasives: Their History and Development," The Norton Co. Searle, "Manufacture and Use of Abrasive Materials," Pitman. Jacobs, "Abrasives Handbook," Penton. "Boron Carbide," The Norton Co. "Abrasive Materials," Annual review in "Minerals Yearbook," U. S. Bureau of Mines.

Natural Abrasives

Diamond of the **bort** variety, crushed and graded into usable sizes and bonded with synthetic resinous and metal powders, finds use in grinding tungsten- and tantalum-carbide cutting tools.

Corundum is a mineral composed essentially of crystallized alumina (93 to 97 percent Al_2O_3) with a density of 3.68 to 3.94, average coefficient of expansion of about 0.0000045 per deg F, and a hardness (Mohs scale) of 9. When of high purity, it is insoluble in acids and melts at close to 3700 F. The present commercial source for corundum is South Africa (Northern Transvaal). Although it has been largely replaced by manufactured abrasives, it is still used in the grinding of lenses and for certain types of rough grinding of steel.

Emery, a cheap and impure form of corundum which has been used for centuries as an abrasive, has been largely superseded by manufactured corundum for grinding. It is still used to some extent in the metal- and glass-polishing trades. The principal deposits of commercial emery are located in Asia Minor and on the island of Naxos.

Garnet. Certain deposits of garnet having a hardness between quartz and corundum are used in the manufacture of abrasive paper. **Quartz** is also largely used for this purpose. In the electrical trades, quartz colored to imitate garnet is sometimes substituted. Garnet costs about twice as much as quartz and generally lasts proportionately longer. Silicon carbide is superior to garnet for leather working.

Grindstones and pulpstones are quarried directly and are generally made from sandstone.

Buhrstones and millstones are generally made from cellular quartz. Chasers (or stones running on edge) are also made from the same mineral.

Oilstones. The great majority of oilstones are quarried in Arkansas and are known as "Arkansas" and "Washita" stones. The **Arkansas stone** is a true novaculite, homogeneous, gritty, and of a fine, siliceous composition. The hard variety is used for sharpening tools requiring a very fine edge, such as those of surgeons, engravers, and dentists. The soft variety is more porous and coarser and is used for less careful work.

Washita stone is less dense, more porous, and of the same general composition. The chief use is for whetstones and for coarser tools.

Pumice, of volcanic origin, is extensively used in leather, felt, and woolen industries and in the manufacture of polish for wood, metal, and stone. An artificial pumice is made from sand and clay in five grades of hardness, grain, and fineness.

Infusorial earth or **tripoli** resembles chalk or clay in physical properties. It can be distinguished by absence of effervescence with acid, is generally white or gray in color, but may be brown or even black. Owing to its porosity, it is very absorptive. It is used extensively in polishing powders, scouring soaps, etc., and, on account of its porous structure, in the manufacture of dynamite as a holder of nitroglycerin, also as a non-conductor for steam pipes and as a filtering medium. It is also known as **kieselguhr, fossil flour,** or **diatomaceous earth.**

The strength of large-sized pieces of structural timber containing knots and other defects is usually not more than two-thirds of the values in Table 1. Table 2 (abstracted from publications of Forest Service) gives results of tests. The strength of small specimens cut from the beams after test is included. The strength of timbers of the same apparent grade varies greatly. The average of the lowest 10 percent group of a series of values will be from 60 to 70 percent of the general average value for the group. The range of individual values, low to high, may be from 50 to 150 percent of the average. Bulletin 108, Forest Service, U. S. Department of Agriculture (Cline and Heim), is an authoritative discussion of tests of large sizes of timber and the effects of defects upon strength. See also Newlin and Johagan, "Tests of Large Timber Columns," *U. S. Dept. Agr. Bull.* 167.

Influence of Knots and Other Defects on Strength. Forest Service tests indicate the following relations: Knots which interrupt the grain in the

* Only those pieces which failed first by horizontal shear are included in this column.

is not possible to obtain as wide a range of grades as by the vitrified method, but the time required in manufacture is relatively short. The process is often used to facilitate quick delivery, and very large diameter wheels can be made with fewer manufacturing hazards. Silicate bonded wheels and shapes give best results on such work as wet tool grinding, knife sharpening, and surface grinding.

Organic Bonded Wheels. Organic bonds can be used for large wheels, and are equally well adapted to the manufacture of very thin wheels because of the flexibility of such wheels as compared with vitrified and silicate process wheels. Organic bonded wheels possess high resistance to centrifugal force and are operated at relatively high speeds. There are three distinct types in the group.

The **shellac process** consists of mixing abrasive grains with shellac, heating the mass until the shellac is viscous, stirring, cooling, crushing, forming in molds, and reheating sufficiently to permit the shellac to set firmly upon cooling. Wheels made by this process are popular for light grinding operations, such as saw gumming, roll grinding, ball race and cam grinding, and in the cutlery trade.

In the **rubber process** the bond is hard rubber. The initial mixture of grain, rubber, and sulphur (and such special ingredients as accelerators, fillers, and softeners) may be obtained by rolling or other methods. Having formed the wheel, the desired hardness may then be developed by vulcanization. Wheels can be made in a wide variety of grain combinations and grades and have a high factor of safety as regards resistance to breakage in service. Wheels made by the rubber process may be used for practically every class of grinding from gear teeth to the snagging of large castings.

The **synthetic resinoid process** is a relatively recent development which is finding an important application in grinding and is revolutionizing many of the older theories regarding grinding wheels and grinding practice. The general practice is to form the wheel by the cold-press process using an especially prepared resinoid. After heating, the resultant bond is an insoluble infusible product of notable strength and resiliency. The resinoid bonded wheel gives promise of largely supplanting the other organic bonded wheels for light grinding. It is also being adapted to the heavy snagging (or rough grinding) of castings and steel billets.

The ordinary abrasive wheel is operated at speeds of 4,000 to 16,000 surface fpm. Abrasive wheels are trued up by a diamond set in the end of a soft metal rod and held against the face of the wheel while revolving.

The **grain** of a wheel is determined by the size or combination of sizes of the abrasive grain used. The Grinding Wheel Manufacturers Assoc. of the United States and Canada has standardized sizes under the arbitrarily assigned numbers 6, 8, 10, 12, 14, 16, 20, 24, 30, 36, 46, 54, 60, 70, 80, 90, 100, 120, 150, 180, 200, 220, and 240. The finer grades known as **flour** are designated as 280, 320, 400, 500, 600, 800, 900, or as F, FF, FFF, and XF.

The **grade** is determined by the hardness of the wheel. The wheel from which the particles are easily broken, causing it to wear away rapidly, is called soft, and one that is able to retain its particles longer is called hard.

The following table gives the most generally used **grade designations** and letter for abrasive wheels:

Grade designation	Very soft	Soft	Medium soft	Medium
	A, B, C,	D, E, F, G	H, I, J, K	L, M, N, O
Grade designation		Medium hard	Hard	Very hard
		P, Q, R, S	T, U, V, W, X	Y, Z

Seasoned wood in small pieces is much stronger than green wood. The relation of strength to moisture content depends upon species, whether softwood or hardwood, and upon the kind of loading.

Table 3 shows the reduction in compressive strength of several woods due to increasing the moisture content from 2 percent to the amount indicated. Thus, red spruce with 16 percent of moisture has but half (0.505) the strength it has with 2 percent of moisture. The latter moisture content could not be maintained in use. The table also serves to permit calculations of change in strength for other changes in moisture content. See also Wilson, *U. S. Dept. Agr. Bull.* 282.

Table 4. Basic Stresses for Clear Timber

(All values are in pounds per square inch)

Species	Extreme fiber in bending	Compression perpendicular to grain	Compression parallel to grain $L/d = 10$	Maximum horizontal shear	Modulus of elasticity

(Not for use in design but for determining working stresses according to the grade of timber and the condition of exposure)

Fish glue is prepared by leaching heads, bones, and other fish scrap. It is sold in liquid form in various concentrations for general gluing work. It is unusually hygroscopic and slow drying. Its greatest importance is in the engraving field.

Casein is obtained by precipitation from cow's milk. It is sold in powdered form and can be brought into solution with ammonia or fixed alkali by heating to not over 150 F. Recently it has become available in cold-water-soluble form. Its principal uses are in laying wood veneer, cork floors, setting brush bristles, etc., where strength and moisture-resistance are desirable and strong alkalinity is no objection. Casein has a tendency to deteriorate unless strongly preserved even after the film has dried out thoroughly. Formaldehyde should be avoided as a preservative because it tends to diminish the solubility of casein.

Vegetable glue is a general classification for all adhesives produced by treating starches or dextrins. The most important sources are wheat, corn, tapioca, sago, and potato starch. These starches lend themselves to various treatments such as cooking with alkali and other chemicals to produce stable liquid solutions. Another method of converting starch into soluble adhesives is by the use of enzymes. In certain cases, an acid treatment is resorted to. Starches can be treated by roasting to produce dextrins from which stable liquid vegetable glues can be produced.

Vegetable adhesives are increasing in use on account of their low cost and convenience, and because they are used cold. Principal uses are in the manufacture of paper bags, paper boxes, envelopes, shoes, and similar lines. The starches or dextrins can be prepared by the consumer. The principal sources of dextrins in the United States are corn, tapioca, and sago. Corn dextrins are not cold-water soluble whereas sago and tapioca are.

Rubber cements are available in two types, the latex or compounded-latex type and the solvent rubber-cement type. Owing to its water-resistance and excellent flexibility, latex is becoming more and more important as an adhesive. Ammonia is used as a stabilizer to prevent coagulation, but deammoniated types have appeared without the objectionable ammonia odor. Latex can be compounded with some glues and pastes to lend them greater adhesive powers.

Solvent rubber cements are produced by dissolving freshly-milled crepe rubber in naphtha with or without the addition of benzol or carbon tetrachloride. This produces a tacky very viscous adhesive which is unusually fast drying but not particularly strong. An objection to its industrial use is its inflammability.

Natural gums are of two types, some being soluble in water, others insoluble. The most important soluble gum is **gum arabic**, from which glue can be produced which is unusually light in color and clear. The insoluble gums, of which **gum copal** and **gum damar** are most generally used, are brought into solution with solvents such as alcohol to produce waterproof adhesives.

Silicate of soda, commonly known as **water glass**, is made by fusing quartz sand with potash or sodium hydrate. It is a heavy oil-like liquid containing 33 to 60 percent sodium silicate and must be protected from air to prevent drying out, or gellation. It is produced in various strengths and used as a cheap adhesive and also for fireproofing cloth and wood. It also finds a use as an ingredient in artificial stone cements.

Miscellaneous. Ordinary **putty** is made from whiting and pure raw linseed oil. Glazier's putty generally contains some varnish in addition. Linseed-oil varnishes mixed with litharge or red lead and ocher are extensively used as a hard-drying putty. **Mastic cement** is composed of powdered limestone, sand, and litharge, mixed with linseed-oil varnish. **Litharge and glycerin** produce a very hard-drying cement, resistant to alkalies, acids, and petroleum solvents. Water glass and chalk produce a hard waterproof mass, as do also water glass and Portland cement. **Magnesia cement** consists of calcined magnesia in a 30 percent solution of chloride of magnesium and hardens to a stonelike mass. **Marine glue** is made from pitch and oils.

ALCOHOL

(See also p. 296)

Grain alcohol (ethyl alcohol) is made by the distillation of fermented sugar solutions derived either from grain, molasses, or fruit sirups, or by the treatment of wood with sulphurous acid. It is sold in the United States

ment and the loss of strength should be taken into account.

The Grading of Structural Timbers

Because of variations in the quality of the wood, the number and size of knots, the degree of cross grain, and the extent of shakes and checks, one timber of a species may be several times as strong as another. Without grading of timbers, working stresses must be adapted to the strength of the poorer pieces of each species. With grading, each piece can be fully loaded and economy and dependability promoted.

In the *U. S. Dept. Agr. Misc. Publ.* 185, there are given proposed specification requirements for grading which take account of the quality of the wood, decay, slope of grain, size of knots in relation to timber dimension, location of knots, size of shakes, and other defects. Different specifications are suggested (1) for beams, girders, stringers, etc.; (2) for joists, rafters, planks, flooring, etc.; and (3) for posts, columns, struts, caps, sills, etc. The influence of these various defects on the strength of the timber is given in the form of **strength ratios** which give the ratio of strength to be anticipated as a percentage of the strength of clear green material.

The major **lumber associations** have graded the structural lumber with which they deal on the basis of the magnitude of the defects, using such terms as "prime," "select," "heart," "merchantable," "common," "No. 1," etc., to indicate the grades. They publish strength ratios for these various grades. A selection of their grades with corresponding strength-ratios is contained in the *Misc. Pub.* 185 already referred to. Further information can be obtained from the California Redwood Association, San Francisco, Calif.; the Northern Hemlock and Hardwood Manufacturers' Association, Oshkosh, Wis.; the Southern Pine Association, New Orleans, La.; the Southern Cypress Manufacturers' Association, Jacksonville, Fla.; the West Coast Lumbermen's Association, Seattle, Wash.; and other regional lumber associations. See also "Wood Structural Design Data," National Lumber Manufacturers Association, Washington, D. C.

The **working stresses** as determined from Tables 4 and 5 must be multiplied by the strength ratios of the lumber associations in order to find the permissible working stresses for lumber of any stated grade.

show no cracking when bent around a 1 in. circular mandrel, grain side outside. Under the piping test, a piece of belting bent 180 deg around a 3 in. mandrel with the grain surface in shall show no signs of coarse wrinkling or piping on the grain surface.

The United States Navy specifications require oak-tanned leather cut entirely from the center or back of the hide and free from any loading. Single belts must show an average tensile **strength** of 4,000 lb per sq in.; double belts a tensile strength of 3,600 lb. When subjected to a stress of 2,250 lb per sq in. for 1 hr, single belts should show not more than 13.5 percent elongation and double belts not more than 12.5 percent. The modulus of elasticity in tension varies from 17,800 lb per sq in. for new belts to 32,000 lb for old. The proportional elastic limit is about 2,300 lb per sq in. The strength of chrome leather varies from 8,500 to 12,900 lb per sq in.

Care of Leather Belting. A harsh dry belt should be dressed by first removing the surface dirt with a coarse cloth and then applying the dressing, a little on the pulley side and more on the outside. Only as much dressing as the leather will readily absorb should be used and preferably when the belt is idle. Neatsfoot oil and castor oil make very good dressings. Surface dressings such as rosin should be avoided, except as first aid in an emergency, for they seriously shorten the life of the belt.

Commercial sizes of leather belting as adopted by the Leather Belting Asso. range from ½ to 72 in. in width, the width increasing by ⅛ in. up to 1 in., by ¼ in. up to 4 in., then by ½ in. to 7 in., and above that by inches.

Rubber belts are made by saturating a strong woven duck belt with rubber and subsequently vulcanizing. Their advantages over leather belts are claimed to be uniformity in width and thickness, durability when exposed to steam and dampness, great tensile **strength**, and grip on pulley. With proper weight of duck, a three- or four-ply rubber belt is claimed to equal a single, and a five- or six-ply to a double leather belt. Rubber belts are cheaper than leather or other belts suitable for the same kind of work and are of particular value in damp locations or under unusual temperature conditions.

Rubber belts should never be treated with animal oils or greases, as these substances rapidly destroy their life. Good results are said to be obtained by painting with a mixture of equal parts of red lead, black lead, French yellow, and litharge mixed with boiled linseed oil and sufficient japan to cause quick drying. This produces a smooth polished surface and, if the belt should slip, the side next the pulley can be slightly moistened with boiled linseed oil. Commercial sizes run from 1 to 60 in., increasing by ⅛ in. up to 2 in., by ¼ in. to 4 in., and then by inches. Special seamless and endless belts can be obtained.

Cotton belts, when woven, have a tensile strength of about 5,000 lb per sq in.; when sewed, from 6,500 to 7,500 lb, per sq in.

BRICK

REFERENCES: "Brick Engineering," Vols. I, II and III, Brick Manufacturers' Assoc. of America; "Brick Structures," Brick Manufacturers' Assoc. of America; Stang, Parsons, and McBurney, "Compressive Strength of Clay Brick Walls," *B. of S. Research Paper* 108. A.S.T.M. Specifications Covering Paving Brick, Building Brick, Sewer Brick and Fire Brick.

Building brick are classified as either common brick or face brick depending on whether or not they have been artificially colored or textured.

Manufactured Abrasives

Manufactured abrasives, although more expensive than the natural, have largely superseded them commercially, owing to a much closer control of chemical composition and crystal structure, thus enabling the maintenance of uniform strength properties or "temper" in the manufactured abrasives.

Crystalline alumina consists essentially of the same mineral as corundum, but the physical properties such as crystal structure, size, and shape of grain are so controlled as to produce the most desirable abrasives for specific types of grinding. The method of cooling the pig of ore and the percentages of impurities present (TiO_2, Fe_2O_3, and SiO_2), although usually less than 5 percent total, greatly influence the properties of the product. Crystalline alumina has a concboidal fracture, and the grains, when crushed or broken, possess sharp cutting points and edges. Manufactured corundum, particularly the fines, is also an excellent refractory material for electric-furnace parts, laboratory ware, and many special industrial installations. As an abrasive it is best adapted to the grinding of high-tensile-strength materials such as steel and annealed malleable iron. Manufactured corundum is available under several trade names such as **Borolon** (Abrasive Co.), **Aloxite** (Carborundum Co.), **Lionite** (General Abrasive Co.), and **Alundum** (Norton Co.). A product made by fusing chemically purified alumina (Al_2O_3) is not so tough as the material of 95 percent purity but is better adapted to certain operations such as precision grinding of sensitive steels.

Silicon carbide (SiC) (see p. 730) corresponding to the mineral moissanite has been found in meteors. The hardness is between that of corundum and diamond; the specific gravity is 3.2. It is insoluble in acid and infusible. It decomposes above 4060 F. It is manufactured by fusing together coke and sand in an electric furnace of the resistance type. Sawdust is used also in the batch and burns away leaving passages for the carbon monoxide to escape. The grains are characterized by great brittleness. Abrasives of silicon carbide are best adapted to the grinding of low-tensile-strength materials such as cast iron, brass, bronze, marble, concrete, stone, and glass. It is available under several trade names such as **Carborundum** (Carborundum Co.), **Carbolon** (Exolon Co.), and **Crystolon** (Norton Co.).

Boron carbide (B_4C), a recent addition to commercial manufactured abrasives, has a scratch hardness greater than that of silicon carbide. It is available under the trade name of **Norbide** (Norton Co.) and is being used in loose grain form for the lapping of tungsten- and tantalum-carbide-type tools. In the form of molded shapes, it is used for sandblast nozzles, wire-drawing dies, bearing surfaces for gages, etc.

Grinding Wheels

Vitrified Process. In wheels, segments, and other abrasive shapes of this type, the abrasive grains are bonded with a glass obtained by mixing the grains with such materials as clays and feldspars in various proportions, forming the mass, drying, and subjecting to heat. It is possible to manufacture wheels as large as 60 in. diam by this process, and even larger wheels may be obtained by building up with segments. Most of the grinding wheels and shapes (segments, cylinders, bricks, etc.) now manufactured are of the vitrified type and are quite satisfactory for general grinding operations.

Silicate Process. Wheels and shapes of the silicate type are manufactured by mixing the grain with sodium silicate (water glass) and fillers that are more or less inert, forming the mass, and baking at a moderate temperature. It

The common requirements are as follows: size, $8\frac{1}{4} \times 2\frac{1}{4} \times 4$, $8\frac{1}{4} \times 3 \times 3\frac{1}{4}$, $8\frac{1}{4} \times 3 \times 4$, with permissible variations of $\frac{1}{8}$ in. in either transverse dimension, and $\frac{1}{4}$ in. in length; loss in rattler test, 22 to 26 percent of original weight.

Although brick have always been used in construction, their use has been limited, until recently, to resisting compressive-type loadings. By adding steel in the mortar joints to take care of tensile stresses, **reinforced brick masonry** extends the use of brick masonry to additional types of building construction such as floor slabs. Reinforced brick masonry behaves like a homogeneous material within its appropriate range of application.

Sand-lime brick are made from a mixture of sand and lime, molded under pressure and cured under steam at 200 F. They are usually a light gray in color and are used primarily for backing brick and for interior facing.

Cement brick are made from a mixture of cement and sand, manufactured in the same manner as sand-lime brick. In addition to their use as backing brick, they are also used below grade for manholes and catch basins where there is no danger of attack from acid or alkaline conditions.

Firebrick. (See p. 728.)

Measuring the amount of **brick required** is done in one of two ways, depending on the types of brick to be used. Where a common brick is to be used throughout the wall, the superficial area in square feet is determined and multiplied by 6(12)[18] for a 4(8)[12] in. wall; this is for masonry joints $\frac{1}{4}$ in. thick. For thinner joints, a slightly larger number of brick are required. Where a face brick is being used with common brick for the backing of a wall, the total number of brick required is determined as above and then the number of face brick is found and subtracted from the total to determine the number of backing brick. For common bond, using a row of headers for every sixth course, the number of face brick required per square foot of wall area is 7. To determine the face brick required for various bonds, increase the number per square foot of area over 6 as follows; for English bond, 50; for Flemish bond, $33\frac{1}{3}$; for Flemish cross bond, $16\frac{2}{3}$; for garden wall bond, 25; for running header bond, 100; for common bond, $16\frac{2}{3}$ percent.

CELLULOID

Celluloid (xylonite, pyralin) is a thermoplastic mixture of nitrocellulose (pyroxylin) and camphor. This material, with the addition of alcohol and pigments or dyes if desired, is pressed or bent into shape in a heated mold. Sp gr is approximately 1.35; easily deformable when warm, but stiff when cold, and about as strong as the softer woods. Modulus of elasticity varies from 200,000 to 500,000 lb per sq in. Chemically unstable at higher temperatures, but stabilized by various admixtures. Very inflammable unless fireproofing agents or other materials are added in large quantities.

CLEANSING MATERIALS

Soap is made by chemically combining fats with alkalies. Most soaps are made by the use of caustic soda; only soft soaps, liquid soaps, and shaving soaps are made by replacing caustic soda in whole or part by caustic potash. Cocoanut oil gives a hard but very soluble soap having a quick, abundant lather, and, therefore, soaps made from this material alone are advantageous for use with hard water. Soaps made from palm oil have a good lather and are readily soluble. Beef tallow is by far the most important material, and the usual soaps on the market contain more tallow than any other material. Olive oil produces a rather soft-bodied soap which becomes firm and hard on aging, of fair lathering properties, and rather slimy feel. Drying and semi-drying oils are usually used only in small amounts, since in neutral soaps

Abrasive Paper

Flint, garnet, emery, corundum, and the artificial abrasives are all used on paper and cloth fastened by glue or some special adhesive. The abrasive papers are used chiefly for soft materials, such as wood, and the abrasive cloths are used for metal work.

Crushed steel is made by heating high-grade crucible steel to nearly white heat and then quenching in a bath of cold water. The fragments thus produced are crushed to particles varying from fine powder up to $\frac{1}{16}$ in. diam and are classified as diamond crushed steel, diamond steel, emery, and steelite. Chief use in the stone, brick, glass, and metal trades.

Rouge and crocus are finely powdered oxide of iron used for buffing and polishing. Rouge is the red oxide, crocus is purple.

ADHESIVES

REFERENCES: J. A. Taggart, "The Glue Book," Inland Printer Co. Bogue, "Chemistry and Technology of Gelatine and Glue," McGraw-Hill. Sherer, "Casein," Van Nostrand. Dulac, "Industrial Cold Adhesives," Lippincott. Standish, "Cements, Pastes, Glues and Gums," Reinhold.

Glue is generally divided into animal glue, fish glue, casein, vegetable glue, latex and rubber cements, natural gums, silicate of soda, miscellaneous.

Animal glue is made by boiling out hides, skins, bones, and sinews of various animals, principally cattle and rabbits, and drying the resulting liquor. It is obtainable commercially in sheets, strips, flakes, ground, and powdered.

The modern method for **grading glue** has been set up and is controlled by The American Glue Manufacturers Assoc. The important properties of glues are viscosity and jelly strength. The viscosity is tested by timing the flow of a definite concentration of glue in water at a set temperature through a pipette. The jelly strength represents the tenacity of a solution of glue that has been allowed to set by cooling to form a jell; it is measured according to the **Bloom Jellometer** and expressed in millipoises. Practically all animal glue bought today is bought in specifications expressed in seconds of viscosity and millipoises of jelly strength. These two properties are most important in the use of the glues and bear a very definite relation to its quality. The higher the jelly and viscosity, the better the grade of glue. Bone glues are usually low in viscosity and jelly strength as compared with hide glues and gelatines.

Undissolved glues will retain their properties indefinitely and will not decay. When brought into solution with water they should be preserved with phenol or a similar powerful preservative. Formaldehyde must be avoided as it tends to reduce the solubility. Good animal glues are neutral or only very slightly acid. The better grades when made up in sheet form will bend without breaking and when broken will show a splintery edge. A clean fracture indicates brittle low-grade glue.

In dissolving, glue should always be soaked in cold water and then warmed. It is of great importance to employ no more heat than necessary to assure complete solution. It should never be heated above 150 F; jacket heat or double boilers should be used but never live steam. The "Glue Book," by Taggart, gives the following valuable suggestions regarding selection:

Wood joints: High-test hide glues. *Veneers:* Moderately high-test mixtures of bone and sinew or, better, bone and hide. *Sizing:* Glue free from grease and foam. *Paper boxes:* Quick setting glues for setting up, low-test glues for covering. *Belting and leather:* High-test glues preferred. *Bookbinding:* For covers, low-grade bone glue; for rounding and backing, high-grade hide glue. For *emery purposes:* Very high-grade and pure glue.

From animal glues are prepared (1) *flexible glue* consisting of a mixture of glue, glycerin, or other plasticizers and water and (2) *liquid animal glues* by treating the raw glue so as to prevent it from jelling. Flexible glue is used principally in the paper-box and bookbinding trade; liquid glues are used for general gluing work.

fittings such as wormline, ratline and spunyarn, also marline and roundline used in serving rigging.

In making cordage, the fiber is opened, run into a sliver (a continuous ribbon of fiber laying parallel and without twist), spun into a yarn, formed *into a strand*, and *laid into a rope*. *Spinning* is twisting the fibers into a continuous length of the size required and with the proper number of twists to the foot. *Forming* is twisting the number of yarns required to make the size of the strand, the twist in the strand opposite to the twist in the yarn.

Ropes are plain laid or cable laid. **A plain-laid rope** may be made of three, four, or six strands twisted together in the opposite direction to the twist in the strand. **Cable-laid** or water-laid rope consists of three plain-laid *three-strand ropes* twisted together in the opposite direction to the twist in the rope. They can be made four or six strand, but such rope is seldom required. Such ropes have approximately 65 percent of the strength of a plain-laid rope of corresponding size. They have greater elasticity and present much greater resistance to abrasive wear and water absorption than plain-laid ropes.

The term **lay** is used to designate the length of one turn in the rope measured parallel to the axis and is usually expressed as hard, medium hard, medium soft, and soft lay. Examples of special lays are yacht rope, bolt rope, sail-maker's lay, coal falls, and transmission lay. A yarn, strand, or rope has S (or left) twist if, when held in a vertical position, the spirals conform in slope to the central portion of the letter S, and Z (or right) twist if the spirals conform in slope to the central portion of the letter Z.

A common-laid rope will have the strength required by the U. S. Government Federal specifications (see below). A soft-laid rope will have less elongation, greater tensile strength, and less resistance to abrasive wear than a hard-laid rope.

Ropes made of selected yarns or bolt-rope stock may be required for severe work. Such rope will exceed the tensile strength required by Federal

Weight and Strength of Different Sizes of Manila Rope, Specification Values

(From U. S. Government Specification TR601A, dated Nov. 26, 1935, and formulated jointly by cordage manufacturers and Government representatives)

Approx diam, in.	Circumference, in.	Max net weight, lb per ft	Min breaking strength, lb	Approx diam, in.	Circumference, in.	Max net weight, lb per ft	Min breaking strength, lb	Approx diam, in.	Circumference, in.	Max net weight, lb per ft	Min breaking strength, lb

5/16	1	0.029	1,000	1	3	0.270	9,000	2¼	7	1.46	41,000
⅜	1⅛	0.041	1,350	1 1/16	3¼	0.313	10,500	2⅝	8	1.91	52,000
7/16	1¼	0.053	1,750	1⅛	3½	0.360	12,000	3	9	2.42	64,000
½	1½	0.075	2,650	1¼	3¾	0.418	13,500	3¼	10	2.99	77,000
9/16	1¾	0.104	3,450	1 5/16	4	0.480	15,000	3⅝	11	3.67	91,000
⅝	2	0.133	4,400	1½	4½	0.600	18,500	4	12	4.36	105,000
¾	2¼	0.167	5,400	1⅝	5	0.744	22,500				

The approximate length of coil is 1,200 ft for diam 7/16 in. and larger. For smaller sizes it is longer; up to 3,000 ft for 3/16 in. diam.

by "degree proof" or "proof," the figure representing twice the percentage of alcohol by volume; thus, 100 deg proof spirit at 60 F contains 50 percent of absolute alcohol. Common custom in the United States expresses the percentage of alcohol "by volume." Grain alcohol is miscible in all proportions with most liquids except fatty oils, which it dissolves very slightly.

Methanol (methyl alcohol), formerly known as **wood alcohol**, is now principally produced synthetically by passing highly compressed hydrogen and carbon dioxide over catalysts, and condensing the reaction product. The material produced in this way is of extreme purity and uniformity. It is waterwhite, and has only a feeble odor. Its specific gravity is 0.7965 at 60 F, and it boils at 152 F. It burns with a non-luminous flame, is miscible in all proportions with water, alcohol, ether, and glycerin, and is a good solvent for certain resinous materials including shellac.

Some methanol is still being made from wood, principally to supply the denaturing trade, which demands certain types of raw materials.

Denatured Alcohol. The object of denaturing alcohol is to permit the use of ethyl alcohol for purposes other than drinking free from the heavy excise tax. The common denatured alcohol of commerce is made under Government regulation by adding a small quantity of wood alcohol and benzine to grain alcohol. Such a mixture is unfit for consumption as a beverage, but for most industrial purposes it serves equally as well as the pure product. For special industries where such a denaturing would be objectionable, the Government has permitted the use of special denaturing materials, such as pyridine, nicotine, "aldehol," sodium salicylate, diethyl phthalate, and a number of other materials.

BELTING

Leather Belts. High-quality leather belting is made of leather cut from the part of the hide which is back of the shoulders and close to the backbone. This section varies from 24 to 32 in. in width and from 40 to 54 in. in length. Such leather is uniform and has minimum stretch and maximum elasticity and produces belts which will run straight and quiet on the pulleys. Single belting can regularly be obtained up to about $\frac{5}{16}$ in. in thickness, double (two-ply) belting up to about $\frac{5}{8}$ in. in thickness. Belting of over two plies is usually made to suit individual conditions. Very wide belting may be made of two or more strips laterally. Extra long sections may include some inferior shoulder stock which is characterized by the coarse neck wrinkles in contrast to firm center stock which is smooth and without wrinkles.

The quality of leather belting may be determined by the "piping" test which consists of taking a piece of belting and doubling it up grain side in. If the wrinkles or piping appearing on the grain side are large and coarse, the leather is not of high quality. Fine, delicate wrinkles indicate firm, sound stock.

The leather most generally used for belting is vegetable tanned, but chrome-tanned and combination-tanned leathers are also used. Leather belting may be regularly obtained which has been made up with waterproof cement, rendering the belt substantially proof against dampness, steam, and water.

The A.P.I. **Tentative Specifications for Leather Belting** (1926) require an elongation of not less than 11 percent nor more than 24 percent for a load of 700 (1,300) lb per in. of width on a single (double) belt. The ultimate strength shall be not less than 700 lb per in. of width for single, and 1,300 lb per in. of width for double belts. A sample of belting must

solvents; drying-oil varnishes based on cashew-nut-shell liquid, combined with resins (Harvel varnishes).

Varnishes have changed greatly in the last few years, since new oils have become available, and particularly since phenolic resins have been employed in their manufacture. The presence of plenty of linseed oil is no longer sufficient evidence of a good varnish, or the finding of rosin evidence of a poor one. Evaluation should be based on performance tests.

Impregnating Compounds. Bitumens and waxes are used to impregnate motor coils, the melted mix being forced into the coil in a vacuum tank, forming a solid insulation when cooled. Brittle compounds, which gradually pulverize due to vibration in service, and soft compounds, which melt and run out under service temperatures, should be avoided as far as possible. Impregnating materials for high-tension paper-insulated cables are usually a blend of petroleum products containing enough thickener to give the right degree of mechanical consistency. Chemical homogeneity of the materials is very important.

Oil. Refined grades of petroleum oils are extensively used for the insulation of transformers, switches, and lightning arresters. The following specification covers the essential points:

Specific gravity, 0.860; flash test, not less than 335 F; cold test, not more than 14 F; viscosity (Saybolt) at 100 F, not more than 120 sec.; loss on evaporation (8 hr at 200 F), not more than 0.5 percent; dielectric strength, not less than 35,000 volts; freedom from water, acids, alkalies, saponifiable matter, mineral matter, or free sulphur. Moisture is particularly dangerous in oil. Skinner claims that 0.06 percent H_2O will reduce the dielectric strength approximately 50 percent.

Paraffin is used to impregnate paper and cloth. Specific inductive capacity, about 2; dielectric strength, 8,000 volts per mm; specific resistance, 240,000,000 to 3,900,000,000 megohms per cu cm.

Impregnated Fabrics. Fabrics serve as a framework to hold a film of insulating material, and must therefore be of proper thickness, texture, and mechanical strength, and free from nap or acidity. Cambric, muslin, lonsdale, and batiste are commonly used (see *Ind. Eng. Chem.*, July, 1928, p. 698).

Empire cloth is cambric treated with linseed oil by a special process. Similar products are oiled linen, oiled canvas, varnished cambric.

Insulating tape, also known as **friction tape** or **binding** tape, consists of a flat woven braid or tape impregnated with an adhesive and insulating compound adhering firmly to the braid. ¾ in. tape should have a breaking strength of not less than 33 lb and run not less than 150 ft per lb; other widths in proportion.

Cumar, or paracumaron resin, is a synthetic resin made from low-boiling coal-tar distillates. It is made in different grades with melting points as low as 120 F and as high as 320 F. As an insulator, it has a dielectric constant somewhat lower than paraffin, but it possesses high surface resistivity particularly when exposed to moist air. It is a neutral resin and unaffected by water, acids, alkalies, and other reagents. It is used in molded insulation in combination with the usual fillers such as asbestos, fiber, pulp, etc. Also used in paint and varnish, rubber compounds, printing inks, and as a substitute for other resins.

Thermosetting substances of the phenol-aldehyde type (Bakelite, Durez, Durite), and of the urea-formaldehyde type (Beetle) first soften and then undergo a chemical reaction which converts them quickly to a strong infusible product. The best all-around properties are available in the phenolics where numerous special types have been developed for high heat resistance (Durez 34), low power factor (Durez 1601, Bakelite XM262).

Common brick are usually red in color due to the iron oxide in the clay. They are used below grade for sewers, manholes, catch basins, tunnels, footings, and foundations, and are used above grade for the facing and backing of exterior walls and for interior partitions.

Face brick may be red in color, but are also available in grays and buffs where fire clays are the basic materials used in their manufacture. By flashing with chemicals, various surface colors such as green, blue, black, yellow, and orange are obtained. Ceramic glazes on face brick are obtainable in almost any color. Various artificial textures lead to such names as "tapestry," "mattex," "vertical scored," "horizontal scored," "oak bark," and "rug." Face brick are used primarily for the facing of exterior walls.

Brick are manufactured by the dry-press, the stiff-mud, or the soft-mud process. The **dry-press brick** is made in molds under high pressure and from relatively dry clay mixes. Usually all six surfaces are smooth and even, with sharp arrises and geometrical uniformity. The **stiff-mud brick** are made from mixes of clay or shale with more moisture than in the dry-press process, but less moisture than used in the soft-mud process. The clay is extruded from an auger machine in a ribbon and cut by wires into the required lengths. These brick may be side cut, or end cut, depending on the cross section of the ribbon and the length of the section cut off. The two faces cut by wires are rough in texture, the other faces may be smooth or artificially textured. The **soft-mud process** uses a wet mix of clay which is placed in molds under slight pressure. Where sand is used to prevent adherence of the clay to the molds, the result is called a **sand-struck brick;** a **water-struck brick** is a soft-mud brick made in molds where water is used as the lubricant.

The various **methods of burning** commonly used are described as scove kilns, tunnel kilns, round or downdraft kilns, continuous kilns, and permanent kilns. The products of the scove kiln are: light hard brick, or tops, coming from the tops and sides of the kiln; body brick coming from the center of the kiln; and bench brick coming from the arches or benches of the kiln. In the round and the permanent kilns and in the continuous kilns, a more even temperature over the entire body of brick allows a greater percentage of body brick. The light hard brick from these kilns come from the sides where the heat is less intense. There are no arch brick or bench brick. In tunnel kilns, all brick are burned approximately the same. Placed on cars, the brick move slowly through the tunnel and into gradually increasing temperatures, until the maximum of approximately 2000 F is reached. From there on, they are gradually cooled.

Brick are highly resistant to freezing and thawing, to attacks of acids and alkalies, and to fire. They furnish good thermal insulation and good insulation against sound transference.

The use of brick masonry in building construction is due primarily to the **strength of brick in compression.** This strength varies according to the hardness to which the brick is burned and according to the clay from which it is made. Strengths of 1,500 to 24,000 lb per sq in. are available. The requirements for brick exposed to the weather are as follows: compressive strength, 4,500 lb per sq in. min; modulus of rupture, 600 lb per sq in. min; absorption, 5 to 12 percent; ratio of 24 hr absorption to porosity as determined by the 5 hr boil test, 80 percent max (see A.S.T.M. "Specification for Building Brick").

Paving brick are made of clay or shale usually by the stiff-mud or dry-press process. Brick for use as paving brick are burned to vitrification.

tensile strength, lb per sq in., 1,800; compressive strength lb per sq in., 15,000; dielectric strength, volts per mm, 16,350. J. E. Boyd (A.S.M.E., Dec., 1915) gives the compressive strength of porcelain and high-grade stoneware as 20,000 lb per sq in.; the tensile strength of porcelain > 3,000 lb per sq in., of stoneware 1,100 to 2,200 lb; the modulus of elasticity in tension and compression of porcelain, 10,000,000 lb per sq in., of stoneware, 6,000,000 to 9,000,000. Much research work has been done on the improvement of porcelain, particularly for spark plugs, resulting in superior material. The pure porcelain is called **mullite, or sillimanite.** Excellent types applied to electrical uses are **isolantite and alsimag.**

Glass finds many special applications in electrical insulation, particularly for low-tension, small-power uses. A new development of interest is glass fiber for the insulation of magnet wire for electrical machinery.

EXPLOSIVES

(Material Contributed by Hercules Powder Co.)

Black Powder is a black granular slow-acting explosive, which does not detonate but burns with explosive rapidity when ignited under confinement. **Gunpowder** and **"A" blasting powder** are made with potassium nitrate, sulphur, and charcoal. **"B" blasting powder** is made with sodium nitrate, sulphur, and charcoal. Black powder is a mechanical mixture of the substances mentioned above, the nitrates furnishing oxygen for the combustion of the inflammable charcoal and sulphur.

The B grade is ordinarily used for blasting. It is used for blasting in non-gassy and non-dusty coal mines and for blasting where a heaving action is desired.

High explosives contain certain chemical compounds which are themselves explosives; they decompose with extreme rapidity.

Nitroglycerin is formed by the action of concentrated nitric and sulphuric acids on glycerin. It is the base of all dynamites. Commercially it is used only for blasting oil wells.

Straight nitroglycerin dynamite consists of nitroglycerin absorbed in a mixture of carbonaceous materials and oxidizing salts. It is very sensitive and has a high rate of detonation in the higher strengths. It is used for demolition, mud capping, submarine blasting, and ditching by the propagated method. It is not recommended for other uses.

Extra (ammonia) dynamite has the same strength, grade for grade, as nitroglycerin dynamite. Ammonium nitrate is substituted in these grades for part of the nitroglycerin. Extra dynamite is less hazardous to handle and use than straight nitroglycerin dynamite and has the advantage of lower cost. Rate of detonation is lower, grade for grade, than the straight nitroglycerin dynamite. It is used for quarrying, stump and boulder blasting, and much general blasting.

High-ammonia dynamite contains ammonium nitrate as the principal explosive ingredient, nitroglycerin being present only in quantities sufficient to give the desired sensitiveness and other properties. These explosives are relatively insensitive to flame, shock, and friction. They are not recommended for wet work. High-ammonia dynamites are used for mining, quarrying, construction, agricultural blasting, and general blasting work.

Blasting gelatin consists principally of nitroglycerin which is gelatinized with nitrocotton. It is a dense rubberlike explosive that is highly water-resistant and has approximately the same strength as nitroglycerin.

larger amounts of these materials would affect adversely the keeping qualities of the soap.

For cleaning paint and varnish, use pure neutral soap and water; any free caustic or carbonated alkali will damage the paint. Unpainted floors are usually washed with soap powder containing large quantities of sodium carbonate. Cleansers for cleaning pots and pans, sinks, baths, etc., usually consist of finely pulverized pumice, quartz, volcanic ash, etc., with small percentages of soap and sodium carbonate.

Soda ash, which is practically pure sodium carbonate, is extensively used for cleaning purposes, and, in solution, as a lubricant for grinding steel dies and cutting steel and as a preventive of rust on steel tools. For the latter purpose, the strength of solution should be kept low. **Sal soda** is a crystalline form of sodium carbonate containing about 63 percent of water by weight. Although extensively used, it can generally be replaced to advantage by soda ash—which should be at least 97 percent pure. **Caustic soda** (sodium hydrate) is extensively used in textile mills for scouring, cleaning, etc., and for cleansing metals from oil and dirt. A good grade should contain not less than 94 percent of caustic soda. It is very hygroscopic.

Caustic potash, used for cleansing, should contain not less than 88 percent of caustic potash; a crude variety, however, containing 65 percent together with considerable caustic soda, is frequently employed. **Carbonate of potash** should contain not less than 75 percent of potassium carbonate.

Solvent naphtha and gasolines, the lighter distillates of coal tar, and petroleum are used to dissolve oil and grease in cleansing metal, fabrics, etc. **Benzol**, in combination with acetone or alcohol is the basis of most varnish removers. **Carbon tetrachloride** is also used as a solvent for oils and grease; it is non-inflammable. **Oxalic acid** is used in solution for the removal of ink and iron stains. **Sodium hydrosulphite**, a bleaching material, is used to remove dye spots from white goods by sprinkling a few dry crystals on the spot, and then directing steam from a small jet at the end of a glass tube onto the crystals. **Ammonia**, a mild alkali, is used to replace the stronger alkalies in cases where damage might result from their use. **Borax** is also used as a mild alkali for cleaning purposes.

CORDAGE

REFERENCES: Printed matter issued by Plymouth Cordage Co.

The term cordage is applied to products made by twisting together a number of vegetable fibers. **Sisal** and **Manila** (structural fibers) are classed as **hard** fibers. **Hemp**—American, Russian and Italian—(bast fibers) is classified as **soft** fiber. **New Zealand flax**, also known as New Zealand hemp, is generally included with the hard fibers (see p. 709). Manila (**abaca**) is the fiber best suited for marine purposes and general construction work.

A Manila rope constructed from good fiber has strength, elasticity, resistance to deterioration and abrasive wear. Mexican sisal has approximately 65 percent of the strength of Manila; it is used where a cheap fiber is required, also for harvest twine. Java and African sisal have approximately 80 percent of the strength of Manila and are commonly used in the manufacture of tying twines and cores for wire rope. Hemp rope is used where softness and pliability are required, such as hand ropes for elevators. Hemp is the best fiber for making tarred cordage as it will absorb tar readily and retain it; hence, its former use for standing rigging and its present use for all tarred

ramie; and vascular fibers. Cotton and ramie are nearly white; linen, grayish brown; jute and hemp have a decided brown color. Those containing large proportions of cellulose are flexible and elastic, while those which are highly lignified or woody are stiff and brittle. The tensile strength varies considerably, but the relative strength of the fibers is in the following order: Hemp, jute, manila, linen, cotton, ramie. Vegetable fibers are much less hygroscopic than wool or silk, the latter averaging 12 to 16 percent of moisture normally, while cotton and linen average but 6 to 8 percent.

Cotton fiber is obtained from the seed hair of the cotton plant, the seeds being separated from the fiber by a process known as "ginning." The small hairs left on the seed after the first ginning, known as "linters," are used in the manufacture of cotton batting, guncotton, etc. The best quality of cotton fiber is known as "Sea Island" cotton, as it is raised on islands off the coast of Carolina.

The natural spiral-like twist of the fiber makes it specially adapted to spinning. The spinning quality is also dependent upon the length and fineness of the staple. Sea Island cotton is spun into very fine yarns, up to 300, *i.e.*, 300 hanks of 840 yd each weigh 1 lb. The tensile strength of cotton is between the tensile strength of silk and wool.

Mercerized Cotton. When cotton is treated with strong caustic alkali and simultaneously subjected to mechanical tension to prevent contraction, the fiber is greatly changed, taking on a high luster and an increase in tensile strength of 30 to 50 percent. The mercerized fiber also has a greater power of absorption for dyestuffs.

Linen is obtained from the flax plant by "retting." The linen fiber consists of nearly pure cellulose. Natural linen varies from pale yellowish-white to grey. It may be bleached with chloride of lime, but the fiber suffers considerable deterioration. It is of pronounced luster, silky in appearance, stronger than cotton, and a better conductor of heat. Its hygroscopic moisture is about the same as cotton. It does not withstand the action of boiling alkalies, bleaching powders, and other oxidizing agents as well as cotton, nor does it dye so readily. Linen can be mercerized in the same manner as cotton.

Jute is obtained from the stalks of the jute plant by steeping in water. The fiber so obtained is free from woody fiber and generally has a length of 4 to 7 ft. It is of pale yellowish-brown color, the best qualities showing a yellowish-white or silver-gray, and having considerable luster and tensile strength. The short fibers are employed as a raw material for papermaking. The fiber is smooth and lustrous and has no jointed ridges or transverse markings, such as in linen or other bast fibers. It cannot be readily bleached owing to the disintegration of the fiber. Its valuable qualities are fineness, silklike luster, and adaptability for spinning. Its strength is less than that of most other bast fibers. Its chief defect is lack of durability, dampness causing rapid deterioration, and under ordinary conditions the fiber becomes brittle and weak. Bleached fiber is especially unstable; its principal uses are in the manufacture of coarse-woven fabrics such as gunny sacks, bagging, binding thread in carpets and rugs. As a substitute for hemp, it has been extensively used in the manufacture of twine and small ropes, and, owing to its cheapness, is largely used to adulterate better fibers.

Ramie and China grass are obtained from the bast of the stingless nettle. They are two distinct fibers, but the names are generally used interchangeably. The fiber is the strongest and most durable of all vegetable fibers and the least affected by moisture. Ramie can be separated into fibers of great fineness and possesses one-third the strength of hemp. It is white in color, resembling bleached cotton, and possesses a higher luster than linen. It lacks the elasticity of wool and silk and the flexibility of cotton, and consequently produces a harsher fabric in which the fine fibers do not adhere well to each other.

Hemp is a name applied to a number of bast fibers of similar appearance and properties, and is obtained from the plant by "retting." Its composition is a mixture of cellulose and lignocellulose. It contains more hygroscopic moisture than cotton or linen. It is principally used for the manufacture of twine and cordage on account of its great strength and durability. It is not readily affected by water as contrasted with jute. It is not much used

specifications 10 to 15 percent. **Coal falls,** generally used as a single whip, and rope used for the transmission of power are made from selected yarns, but because of the hard lay are not so strong as common-laid rope made of fiber of the same grade.

Drilling cables are a cable-laid product. They are generally left laid but can be made right laid and from selected yarns if required.

ELECTRICAL INSULATING MATERIALS

REFERENCES. Murphy and Morgan, "The Dielectric Properties of Insulating Materials," *Bell System Tech. Jour.*, 16, Oct., 1937, p. 493. Taylor, "Evaluation of Plastics," *India Rubber World*, 98, May, 1938, p. 41.

The insulating properties of any material are dependent upon: dielectric strength or the ability to withstand high voltages without breakdown; ohmic resistance or the ability to prevent leakage of small currents; and power loss or the absorption of electrical energy, which is transformed into heat. Power loss depends upon a number of influences, particularly the molecular symmetry of the insulation and frequency of the voltage, and is the basis of power factor, an important consideration whenever efficient handling of alternating currents is concerned, and a dominating consideration when high frequencies are used, as in radio circuits. Materials may have one of these qualities to a far greater extent than the other, for example, air has a very high specific resistance but very little dielectric strength and no power loss at any frequency; glass has great dielectric strength yet much lower resistance than air. The **ideal insulator** is one having the maximum dielectric strength and resistance and also mechanical strength and chemical stability. Moisture is by far the greatest enemy of insulation, consequently the absence of hygroscopic quality is desirable.

The common insulating materials are described below. For their electrical properties, see p. 1706.

Rubber. See Rubber, Gutta Percha, and Balata, p. 724

Mica and Mica Compounds. Mica is a natural mineral varying widely in color and composition, and occurs in sheets which can be subdivided down to a thickness of 0.00025 in. White mica is best for electrical purposes. The green shades are the softest varieties, and the white amber from Canada the most flexible. Mica has high insulating qualities, the best grades having a disruptive strength of 12,000 rms volts per tenth of a millimeter. Its lack of flexibility and non-uniformity and its surface leakage are disadvantages. To offset these, several mica products have been developed, in which small pieces of mica are built up into finished shapes by means of binders such as shellac, gum, and Bakelite. Mechanical strength: modulus of rupture (beam tests) 50,000 to 70,000; modulus of elasticity 25,000,000 to 30,000,000; shearing strength 18,000 to 38,000 lb per sq in.

Micanite consists of thin sheets of mica built into finished forms with insulating cement. It can be bent when hot and machined when cold, and is obtainable in thicknesses of 0.01 to 0.12 in. Flexible micanite plates, cloth, and paper are also obtainable in various thicknesses. **Mogohmit** is similar to micanite except that it is claimed not to contain adhesive matter. It can be obtained in plates, paper, linen, and finished shapes. **Megotalc,** built up from mica and shellac, is similar to the above-named products and obtainable in similar forms.

Insulating Varnishes. Three general types of insulating varnish are used: asphalt, bitumen, or wax, in petroleum solvent; drying-oil varnishes based on linseed, chinawood, perilla, or soybean oil, compounded with resins from natural or synthetic sources, thinned principally with petroleum

all over the receptacle. It also tends to corrode metals. For freezing temperatures, see p. 1879.

Calcium chloride ($CaCl_2$) is a white solid substance widely used for preventing freezing of solutions and (owing to its great hygroscopic power) for keeping sizing materials and other similar substances moist. It does not "creep" as in the case of salt. It does not rust metal but attacks solder.

Calcium chloride solutions are much less corrosive on metal if made alkaline by the use of a little lime, and also if a trace of sodium chromate is present. They are not suitable for use in automobile radiators, because of corrosive action while hot, and because of tendency of any spray therefrom to ruin the insulation of spark plugs and high-tension cables. For freezing temperatures see p. 1879.

Glycerin is a colorless, viscid liquor without odor and miscible with water in all proportions. It should have a specific gravity of approximately 1.25. It has no effect on metals but disintegrates rubber and loosens up iron rust.

Denatured alcohol is free from the disadvantages of calcium chloride, salt, and glycerin solutions, but is volatile from water mixtures which run hot. A solution containing 50 percent alcohol becomes inflammable, but it is rarely necessary to use more than 30 percent. Cost, approximately 50 cents per gal. See p. 693.

Methyl alcohol (Zerone), variously trade named, is sold widely for automobile antifreeze. It is a desirable and effective antifreeze, but care must be taken not to breathe its fumes, which are poisonous.

Ethylene glycol (Prestone, Zerex) is used as a freezing preventive and also permits the use of high jacket temperatures in aircraft and other engines. Sp gr 1.125 (1.098) at 32 (77) F; boiling point, 387 F; specific heat, 0.575 (0.675) at 68(212) F. Miscible with water in all proportions.

Non-freezing Percentages by Volume in Solution

Temp. deg F	20	10	0	−10
Methyl alcohol	13	20	25	30
Prestone	17	25	32	38
Alcohol	17	26	34	42
Glycerine	22	33	40	47

GLASS

REFERENCES: Journal of the Society of Glass Technology, Sheffield, England. Hodkin and Cousen, "A Textbook of Glass Technology," Van Nostrand. Hovestadt, "Jena Glass," Macmillan. Rosenhain, "Glass Manufacture," Van Nostrand. Long, "Propriétés physiques et fusion du verre," Dunod. Dralle-Keppeler, "Die Glasfabrikation," vols. 1 and 2, Oldenbourg. Eitel-Pirani-Scheel, "Glastechnische Tabellen," Springer. Jebsen-Marwedel, "Glastechnische Fabrikationsfehler," Springer.

Glass is obtained by melting together silica, alkali, and stabilizing ingredients, such as lime, alumina, lead, and barium. Bottle, plate, and window glass, usually contain SiO_2, Al_2O_3, Fe_2O_3, CaO, MgO, and Na_2O. Small amounts of the oxides of manganese and selenium are added to obtain colorless glass.

Special glasses, such as tableware, laboratory ware, thermometer glass, and optical glass, *require different manufacturing methods and different compositions.* The following oxides are either substituted in or added to the above base glass: B_2O_3, ZnO, K_2O, As_2O_3, PbO, MnO, etc., to secure the requisite properties. Colored glasses are obtained by adding the oxides of iron, manganese, copper, cadmium, cerium, titanium, etc.

Molten glass possesses the ability to be fabricated in a variety of ways and to be cooled down to room temperature rapidly enough to prevent crystallization of the con-

arc resistance (Bakelite XM1000), and other specialized properties. Materials are available for such specialized applications as the molding of telephone handles (Durez 1543), radio-tube bases (Durez 2260T), and automotive ignition parts (Durez 2491). The urea plastics are lacking in heat resistance but are suitable for general-purpose molding and have fair arc resistance.

Paper. The present tendency is to use paper only as a backing or framework for an insulating film or compound, owing to hygroscopic qualities. Manila and **kraft** papers possess the best dielectric and mechanical strength, and when coated with good insulating varnish are excellent insulators. **Japanese paper** is extremely thin and strong, and is used in tubular insulation and also as a backing for mica paper. Various types of paper, paraffined, are used in condensers.

Vulcanized fiber, also known as **hard fiber,** is prepared by treating paper pulp or a textile material with a saturated solution of zinc chloride and afterward consolidating it under heavy pressure. The soluble materials are then carefully leached out by long soaking in water and the fiber dried out. It has a consistency like horn, but is generally found, in commerce, treated with glycerin or glucose, which makes it very pliable. In the hard form, it can be planed, sawed, and worked like wood, and in the soft form can be readily molded. It is claimed to be an efficient non-conductor of heat and an excellent insulator. The soft varieties are used in making artificial leather and rubber products. Its **specific gravity** is about 1.3; **specific resistance,** 53 megohms per cu cm. Furnished in 42 × 66 in. sheets 0.010 to 1½ in. thick, and in tubes ³⁄₁₆ in. to 2½ in. diam by 22 to 36 in. long. It must be thoroughly seasoned, tough and flexible, and, when unbaked, must stand bending around a circle having a radius of 10 times its thickness without cracking or splitting. After 12 hours' baking at 250 F, it must bend around a circle of radius 50 times its thickness. **Tensile strength** of sheets, lb per sq in.: less than ¹⁄₁₆ in. in thickness and over ⅝ in., 5,000; ¹⁄₁₆ in. to ¼ in., 8,000; ¼ in. to ⅝ in., 7,000 lb per sq in. **Electrical strength:** about 1,200 volts per 0.01 in. of thickness.

Presspahn or **fuller board** is a specially prepared paper board which, when impregnated with oil, is an excellent insulator. Insulator presspahn is very hygroscopic. The material is mechanically strong but its dielectric strength is greatly injured by creasing. **Pergamyn** is cellulose beaten into fine fibrillae and consolidated under pressure without gelatinization or chemical treatment. Its uses are similar to those of vulcanized fiber. **Cellulith** is produced by grinding wood pulp to a homogeneous mass and then drying. It is very hard, can be worked like wood, and is claimed to be a substitute for horn or ebonite. **Isolit** is a form of papier maché impregnated and covered with special insulating compound. **Adit** is a variety of isolit claimed to have great tensile strength and toughness and to ignite with difficulty. **Litholite** is a paper product used for insulation. It has high disruptive strength; good insulation resistance, and is stated to be inflammable but tough. **Psychiloid** is a chemically treated paper pulp obtainable in sheets from ¹⁄₁₆ in. to 1½ in. in thickness. It is very strong and rigid, and stated to have high disruptive strength and insulation resistance.

Porcelain is made from the purest white clay agglutinized by some substance such as powdered feldspar which softens and fuses at the temperature at which the ware is fired, rendering the mass semitransparent. The material possesses great solidity, strength, and ability to resist sudden changes of temperature. It is used extensively for electrical purposes on account of its strength, durability, and electrical resistance. External glaze is of importance in protecting porcelain. A simple test for quality consists in chipping off the glaze and noting whether ink produces a flowing stain, which it will do on poor grades. **Properties:** The Locke Insulator Mfg. Co. gives the following average values: specific gravity, 2.427; specific inductive capacity, 4.4;

Luxfer prisms are white glass plates whose interior side is provided with parallel prismatic, transverse ridges. They are mounted vertically in front of windows or as protecting roofs more or less obliquely on the outside, and serve to diffuse the light passing through them into the darker portion of the apartment. They possess great strength and considerable resistance to fire.

Pyrex glass is a low-expansion borosilicate glass containing no metals of the magnesia-lime-zinc group and no heavy metals. Physical properties: modulus of elasticity 8,800,000 lb per sq in.; sp gr 2.25; refractive index 1.4754; dispersion 0.00738; linear thermal expansion coefficient (65–660 F) 0.0000032; specific heat 0.20; thermal conductivity 0.21 Btu per sq ft per in. per deg F per hr; can be used without softening up to 1200–1300 F. Principal uses are chemical ware, baking ware, high-tension insulators, sight glasses for chemical apparatus, boiler gage glasses, glass pipe lines for chemical plants, railroad lantern globes and battery jars. Owing to its low coefficient of expansion, Pyrex glass withstands sudden changes of temperature without breaking. Chemical ware withstands the test of plunging from molten paraffin at 390 F into ice water.

Fused quartz is made by melting rock crystal or purest quartz sand in the electric furnace. It is unaffected by changes of temperature, is fireproof and acid-resistant, does not conduct electricity, and has practically no expansion under heat. It is used considerably for high-temperature laboratory apparatus. (Paget, *Jour. Royal Society of Arts*, Apr. 4, 1924.)

GRAPHITE

REFERENCES: "Graphite, Its Properties, Occurrence, Refining and Uses," Department of Mines, Canada. "Mineral Resources of the United States," U. S. B. of M. Acheson, "Seventeen Years of Experimental Research and Development," Am. Acad. of Arts and Sciences, 1908. "Mineral Industry." Seton, "Graphite and Its Uses." *Jour. Soc. Chem. Ind.*, **43**, 1939. Vosburgh, "Electrodes—Carbon and Graphite," *Elec. Eng.*, **52**, 1933. Szymowitz, "Colloidal Graphite," *Jour. Chem. Educ.*, **16**, 1939.

Graphite is an amorphous form of carbon, other forms being the diamond and lampblack. Three commercial varieties are obtainable—flake, amorphous, and artificial. Flake and amorphous graphite exist in nature and are separated from their accompanying rock mechanically. The latter is much more abundant but of less value commercially. The best flake graphite comes from Ceylon, although certain valuable varieties occur in the United States, particularly those in New York State controlled by the Jos. Dixon Crucible Co. The **specific gravity** of commercial graphite ranges from 2.015 to 2.583; for refined graphite it is 1.802. Its **hardness** on Mohs scale is between 1 and 2. The **specific heat** of natural graphite is 0.2019; of furnace graphite, 0.1970. The **heat value** of natural graphite is 14,033 Btu (Favre and Siberman), and of artificial graphite, 14,222 Btu (Berthelot and Petit) per lb. According to Fizeau, the **coefficient of linear expansion** per deg F is 0.00000437 at 104 F, and the elongation of a unit length from 32 to 212 F is 0.000796. Graphite conducts heat better than diamond and is also a good conductor of electricity.

Specific electrical resistance: Natural, 14.20 ohms (Streintz), 12.20 ohms (Muraoka); graphitized electrode, 12 ohms; Ceylon, 2 to 8 ohms (Zellner); Acheson electrode, 12 ohms (Zellner).

Flake graphite is extensively used in the manufacture of crucibles and other refractories, owing to its resistance to heat and its ability to form a stiff mix with clay. It is also used in stove polish, foundry facings, paint and pencil manufacture, and as a lubricant.

Amorphous graphite is extensively used in paints owing to its resistance to acids and alkalies and ability to form an elastic film with oil; also for packings, lubrication, electrodes, and pencils. For lubrication, it must be entirely free from grit; owing to its unctuous nature, it is an excellent lubricant either alone or with oil.

Straight-gelatin dynamites are made in various strengths and are dense plastic water-resistant explosives with fumes that make them suitable for underground use. The nitroglycerin used in gelatin dynamites is gelatinized with a small percentage of nitrocotton, which is responsible for their consistency. These explosives have been almost entirely replaced by **extra gelatins** or **ammonia gelatins**, which contain ammonium nitrate.

Semigelatins contain a higher percentage of ammonium nitrate than extra gelatins. They are more economical and possess sufficient plasticity and water-resistance to make them suitable for much work formerly requiring gelatin. They are more economical than gelatins, and their fumes are such that they are suitable for most underground work.

The gelatins and semigelatins are used in mining, quarrying, construction, tunnel driving, shaft sinking, and for other uses where their water-resistance, fumes, or plasticity make them specially adapted.

Permissible explosives are explosives similar in all respects to samples which have passed certain tests by the U. S. Bureau of Mines and when used in accordance with the directions prescribed by that Bureau. Permissible explosives are used in coal mining and particularly recommended for use in gassy and dusty mines. There are two general classes; nongelatinous permissibles, which are used for most work; and gelatinous permissibles, which are especially adapted for wet conditions.

FIBERS

REFERENCES: Matthews, "The Textile Fibers," Wiley. Graff, "Color Atlas for Fiber Identification," Inst. of Paper Chem., 1940. Hünlich, "Textile Fibers and Materials," Skinner. Astbury, "Fundamentals of Fiber Structure," Oxford. Hess, "Textile Fibers and Their Use," Lippincott.

Fibers for industrial purposes are either mineral, animal, or vegetable. They may be further classified as natural and synthetic. The principal mineral fiber of importance is asbestos (see p. 717). Finely spun glass, slag wool, and metal threads are also used. The animal fibers of commercial importance are either animal hairs or the silk of the silkworm and the larvae of other moths. Sheep, goats, and camels supply the principal hair fibers. Cotton, linen, jute, and hemp are the principal vegetable fibers of natural origin, and rayon is the most important synthetic fiber.

Fibers may readily be distinguished under the microscope. Animal and vegetable fibers may be distinguished by their odor on burning, and by the fact that vegetable fibers burn off sharply while animal fibers fuse to a rounded beadlike end.

Animal Fibers

Silk fiber consists of a continuous thread spun by the mulberry silkworm. Inferior silks are obtained from other varieties of caterpillars and are known as "wild" silk.

Silk fiber possesses great tensile strength, the average breaking strength being approximately 64,000 lb per sq in., and the elongation 15 to 20 percent.

Wool. The wool of the sheep is that principally employed. The tensile strength and elasticity of wool fibers vary widely; the average strength being about half that of cotton. The length of the fiber varies between 1 and 8 in. and the diam between 0.0018 and 0.004 in. Wool is graded according to the length of staple into "tops" and "noils," the former being used for worsted yarns and the latter for making woolen and carded yarns.

Vegetable Fibers

All vegetable fibers consist mainly of cellulose and may be classified as follows: seed hairs, such as cotton; bast fibers, such as flax, hemp, jute, and

which has the most complete and most finely divided cellular structure. The obstruction to heat flow is offered by the surface resistances at the boundaries of the air space. Air itself is not a good insulator. The material should not absorb moisture and should be free from rot, mold, or offensive odors. The principal materials used for this purpose are cork, asbestos, and mixtures of asbestos and magnesia and mineral wool.

Cork is the outer bark of the cork oak. It is highly compressible, possesses great permanent elasticity, is an excellent nonconductor of heat, is waterproof, unaffected by moisture, and slow burning. The natural cork wood weighs 10 to 12 lb per cu ft. Cork is used for bottle stoppers, life preservers, cold-storage insulation, carburetor floats, polishing wheels, washers and gaskets, cork paving brick, isolating pads for machinery, and in the manufacture of linoleum and cork tile flooring.

For cold-storage insulation, pure corkboard is made in sheets 12 in. × 36 in. × thicknesses up to 6 in. No artificial binder is used, the natural gums and resins in the cork sufficing to hold the material together after proper baking. The **U. S. Navy Department** specification requires that such pure corkboard shall withstand boiling in water for 3 hr without disintegration or more than 2 percent expansion in any direction. Granulated cork is likewise used for cold storage insulation as a filling material between confining walls. Granulated cork ordinarily refers to new corkwood finely divided, while the term regranulated cork applies to the granulated material which has been baked in making corkboard and which is a by-product of this material. Tests made at the Bureau of Standards give the following values of heat conductivity for cork products in Btu per sq ft per in. thickness per deg F per 24 hr: corkboard, no artificial binder, density 6.9 (9.9) [11.3] lb per cu ft, 6.5 (7.3) [7.4]; corkboard with bituminous binder, density 16 lb per cu ft, 8.4; ground cork, less than $\frac{3}{16}$ in., density 9.4 lb per cu ft, 7.1; regranulated cork, about $\frac{3}{16}$ in., density 8.1 lb per cu ft, 7.5. The pure corkboard used commercially weighs approximately 10½ lb per cu ft (see also Tables 4 and 6, pp. 389, 390).

Cork tile, made by essentially the same process as pure corkboard, is a quiet, non-slippery floor largely used for bank working spaces and in public libraries.

Linoleum is a mixture of cork dust with linseed and other drying oils, reinforced on one side by burlap material. Machinery isolation is made from pure cork baked under pressure in thicknesses up to 6 in.

Balsa is the wood of a large tropical tree found in Latin America. It is the lightest wood known, commercial grades weighing 8 to 15 lb per cu ft. When properly prepared, over 90 percent of the volume of the wood consists of air spaces. U. S. Bureau of Standards tests show conductivity of 7.5 to 8.3 Btu per sq ft per in. thickness per deg F in 24 hr. Tests at the Massachusetts Institute of Technology show about half the strength of spruce; weight, kiln dry 7 to 11 lb per cu ft; modulus of rupture 2,357 lb per sq in; maximum crushing strength in compression parallel to grain 2,317 lb per sq in.; shearing strength parallel to grain 351 lb per sq in. Natural balsa is subject to decay. It can be made waterproof and non-absorbent to oil and gasoline. It can be sawed, planed, and worked like ordinary wood, and painted, stained, or varnished. Largest commercial size of balsa boards is 4 in. × 6 in. × 6 ft. Principal uses: refrigerator lining, life preservers, floats, and other purposes where lightness combined with strength is desired.

Diatomaceous silica is a mineral of low density consisting of the fossilized cellular skeletons of microscopic organisms called diatoms. Other names for

for woven textiles on account of its harshness and stiffness and lack of pliability and elasticity. The fiber is of dark brown color and cannot be successfully bleached without injury.

Manila hemp is obtained from the leaf stalks of the *Musa textilis*. The fiber is white and lustrous, light and stiff, easily separated, very strong, and of great durability. The coarser fibers are used for the manufacture of cordage on account of their great strength. Manila hemp ropes are stronger than cotton ropes.

Sisal hemp is obtained from the leaves of a plant found in Central America, and to some extent in the West Indies and Florida. It is of light-yellowish color, straight and smooth. Its principal use is in cordage manufacture, its strength being second only to that of Manila hemp. It is also used for papermaking.

Waste. The best **wool waste** consists of all-wool carpet yarn in threads not less than 3 in. long and comparatively free from moisture or dirt. **Cotton waste** should consist of equal parts of white and colored new cotton threads properly mixed and free from water and dirt. White cotton waste should be made up entirely of new white cotton threads not less than 3 in. long and free from dirt or water. It is customary to purchase waste by sample. Inferior quality is indicated by the presence of fibers other than wool or cotton, by sweepings or dirt, or by evidence that the waste has been previously used.

Synthetic Fibers

Rayon of several types (nitrocellulose, cuprammonium, viscose, cellulose acetate) is produced by the extrusion of a cellulose solution obtained from cotton linters or purified wood pulp, dissolved in one of several cellulose solvents, through the fine holes of a spinneret into air or a hardening bath, to form a continuous filament. Several such filaments are twisted to form a thread. A wide range of filament diameters is possible from very coarse to finer than silk, and by a modification of the extrusion orifices, **cellophane**, hollow tubes, and artificial bristles may be produced. Rayon thread is being used in tire fabric because of its excellent heat resistance. When wet, most rayon fibers lose strength.

Glass wool, made from molten glass by methods similar to those used in the manufacture of slag wool from molten rock or slag, can be produced in a wide variety of filament diameters. The coarser material is extensively used in filters for air conditioning and is widely used for thermal insulation. The finer fibers can be woven into cloth of unusual chemical inertness, strength, fireproofness, durability, and electrical resistance. Woven glass tape is used for electrical insulation, and glass cloth for filtration involving corrosive liquids.

Casein wool, or **prolon**, made from milk casein, **wood wool** made from cellulose but permanently crimped in manufacture, and **synthetic bristles** made by the interaction of an organic acid and an amine to produce an organic salt capable of being formed into filaments of varying thickness, are other synthetic fibers. **Exton** is coarse fiber for bristles and **nylon** is finer fiber either for bristles or for yarn. **Vinyon** is a vinyl acetate-vinyl chloride extruded fiber, used for yarn.

FREEZING PREVENTIVES

Common salt is sometimes used to prevent the freezing of water; it does not, however, lower the freezing point sufficiently to be of use in very cold weather, and in concentrated solution tends to "creep" and to crystallize

Mineral wool and **glass wool** are fibers made by the steam blowing of molten slag or glass. Bats of these substances should be of fine fibrous structure and as free as possible of lumps.

Hair felt is made from lime-washed cattle hair formed into felts from 1/4 to 2 in. thick. It is used for the insulation of refrigerator cars and for insulation of piping, fittings, and tanks at low temperatures. It is also furnished stitched between layers of waterproof paper for various low-temperature insulation purposes and between layers of asbestos paper for passenger-car insulation.

Vegetable fiber insulations, in the form of boards 7/16 to 1/2 in. thick, made from wood pulp or bagasse, are widely used in frame-building construction. In addition to having considerable insulating value, they possess sufficient structural strength to replace wood sheathing and plaster lath. They are also used in the construction of refrigerators, refrigerator cars, etc. Finely divided wood or other vegetable fibers secured between layers of paper are used for frame building insulation, etc.

For commercial insulating materials, see also pp. 389–391. For commercial pipe coverings, see also p. 953.

LACQUERS

From 1926 until about 1937 practically all automobiles were finished with duco or other pyroxylin lacquers. Some cars still are finished with pyroxylin, but the trend toward the use of baked enamels is very marked. Pyroxylin has the advantages of requiring about one-tenth the time necessary for paint and varnish and of better resistance to weather and usage.

The foundation or film-making material used in lacquers is nitrocellulose or pyroxylin, largely of so-called low-viscosity type. This is improved in flexibility and color dispersion by the use of plasticizers, and improved in body, density, waterproofness, adhesion, and gloss by the use of various resinous materials. All colors are obtained by pigments which must be of extreme fineness and well dispersed, and capable of withstanding indefinite exposure to sunlight and rain without fading.

The liquid portion of lacquers consists of solvents and diluents which for spray application boil mostly between 212 and 280 F, but small amounts boiling lower or higher are permissible or desirable for certain purposes. In general, pyroxylin lacquers dry by evaporation of the solvent, but several types depend upon the oxidation of some drying oils in addition to the first-set of the pyroxylin by evaporation.

Some use is made of lacquer for the inside finishing of houses, offices, and hotels, where speedy drying is essential. Lacquer is also being used on railroad cars, but, so far, not extensively for out-door large-scale painting. In general, pyroxylin lacquer has not body enough for satisfactory use on furniture or other woodwork, but is used on a few items, such as radio cabinets.

LEATHER

Belts. See Belting, p. 699.

Rawhide is prepared by rubbing oil or fats into a strip of hide, twisting and stretching it until the moisture is removed and the skin thoroughly filled with oil. It is very strong, tough, and waterproof, and is chiefly used for belt lacing and similar purposes.

Leather substitutes generally consist of refuse leather reduced to a pulp, molded, pressed, or wound into suitable shapes, and frequently waterproofed by a final treatment. The earlier of these preparations were composed of glue, starch, waxes, and adhesives and also included water-repellent ingredients. Of the leather-free artificial leathers, of which there are many types, the best known are **leatherine,** made by coating calico with rubber and rubber substitute; **leather board,** prepared by pulping fibrous materials

stituents. It is a rigid material at ordinary temperatures, but may be remelted and molded any number of times by the application of heat. Ordinary glass is melted at about 2600 F and will soften enough to lose its shape at about 1100 F.

Properties of Glass. *The following data are for ordinary glass: specific* gravity, 2.3 to 2.6; tensile strength, 10,000 lb per sq in.; compressive strength, 50,000 lb per sq in.; modulus of elasticity, 10,000,000 lb per sq in.; coefficient *of expansion,* 40 to 60 $\times 10^{-7}$ per deg F; thermal conductivity, 0.4 to 0.6 Btu per sq ft per in. per deg F per hr; specific heat, 0.16 to 0.20.

Glass always breaks under a tensile stress which arises in the system, even though it fails under an applied compressive force. The value obtained for crushing strength depends on the material of the plates used and upon the precision of the testing apparatus. Glass resists atmospheric corrosion and is one of the best materials for resisting the attack of water, bases, and acids, with the exception of hydrofluoric acid.

Window glass is a soda-lime-silica glass, fabricated in continuous sheets up to a width of 6 ft. The sheets are made in two thicknesses, SS and DS, which are, respectively, $\frac{3}{32}$ and $\frac{1}{8}$ in. Both thicknesses are made in A, B, C, and D grades.

Plate glass is similar in composition to window glass. It is fabricated in continuous sheets up to a width of 15 ft, and is polished on both sides. *It may be obtained in* various thicknesses and grades.

Skylight Glass. The weight of fluted or roof plate glass required for one square of roof (no allowance being made for lap) is approximately 350 lb for $\frac{1}{4}$ in. glass; in proportion for other thicknesses. A square of roof is 10 ft square.

Safety glass consists of two layers of plate glass firmly held together by an intermediate layer of organic material, such as pyroxylin plastic or cellulose acetate. The *safety glass, which is sealed to prevent deterioration of the plastic layer, is ordinarily* $\frac{1}{4}$ in. thick, but can be obtained in various thicknesses. This plate is shatterproof and is used for windshields, bank cashier's windows, etc.

Toughened glass is made from sheet glass in thicknesses up to 1 in. It possesses great mechanical strength, which is obtained by rapidly chilling the surfaces while the glass is still hot. This process sets up a high compression on the glass surfaces, which have the capacity of withstanding very high tensile forces before failure occurs.

Wire glass is a glass having an iron wire screen thoroughly embedded in it. It offers about $1\frac{1}{2}$ times the resistance to bending that plain glass does; very thin sheets may be walked on. If properly made, it does not fall apart when cracked by shocks or heat, and is consequently fireproof. It is used for flooring, skylights, fireproof doors, fire walls, etc. It must be ordered exactly to measure, as it cannot be readily cut. Less light passes through it than through plain glass.

Pressed glass is made by forming heat-softened glass in molds under pressure. Such articles as cheap tableware, insulators, and glass blocks are made by this process.

Glass insulators are pressed and are made in a variety of shapes and sizes for both low and high voltages. Glass is a good conductor in the molten condition, but is a good insulator at ordinary temperatures. The dielectric constant and specific resistance of glass can be varied within wide limits, making it an ideal material for many electrical purposes.

Glass blocks find wide application for building purposes, and are made $3\frac{7}{8}$ in. thick in the following sizes: 5 $\times$ 8, 6 $\times$ 6, 8 $\times$ 8, 12 $\times$ 12 in. The thermal conductivity of a glass block panel, for a thickness of $3\frac{7}{8}$ in., is 0.49 Btu per sq ft hr per deg F. The solar heat transmission can be varied within wide limits by using different colored glasses and by changing the reflection by means of surface configurations. The light transmission can be varied from 25 to 80 percent by changing the surface configurations of the blocks.

Fiber glass is a term used to designate articles that consist of a multitude of tiny glass filaments ranging in size from 0.0001 to 0.01 in. in diam. The larger fibers are used in air filters; those 0.0005 in. in diam, for thermal insulation; and the 0.0001 to 0.0002 in. diam fibers, for glass fabrics, which are stronger than ordinary textiles of the same size. Insulating tapes made from glass fabric have found wide application in electrical equipment, such as motors and generators.

Vitrolite structural glass is used for many structural purposes, such as store fronts and table tops, and is available in thicknesses of $\frac{5}{16}$ and $\frac{7}{16}$ in., and 128 $\times$ 177 in.

Properties of Common Minerals*

Mineral	Composition	Hardness, Mohs scale	Specific gravity
Amphibole	$Ca_5(ClF)(PO_4)_3$	5.0	3.2
Andalusite	Al_2SiO_5	7.5	3.1 to 3.2
Anhydride	$CaSO_4$	3.0 to 3.5	2.9 to 3.0
Apatite	$Ca_5(ClF)(PO_4)_3$	5.0	3.2
Aragonite	$CaCO_3$	3.5 to 4.0	2.9
Barite	$BaSO_4$	2.5 to 3.5	4.3 to 4.6
Bauxite	$Al_2O(OH)_4$	1.0 to 3.0	2.4 to 2.5
Biotite	$(HK)_2(MgFe)_2Al_2(SiO_4)_3$	2.5 to 3.0	2.7 to 3.1
Borax	$Na_2B_4O_7.10H_2O$	2.0 to 2.5	1.7
Calcite	$CaCO_3$	3.0	2.7
Chrysolite	$(MgFe)_2SiO_4$	6.5 to 7.0	3.3 to 3.6
Corundum	Al_2O_3	8.5 to 9.0	3.95to 4.1
Cryolite	$AlNa_3F_6$	2.5	2.9 to 3.0
Cuprite	Cu_2O	3.5 to 4.0	5.8 to 6.1
Dolomite	$CaMg(CO_3)_2$	3.5 to 4.0	2.8 to 2.9
Epidote	$Ca_2(AlFe)_2(AlOH)(SiO_4)_3$	6.0 to 7.0	3.2 to 3.5
Garnet	$(SiO_4)_3$	6.5 to 7.5	3.1 to 4.3
Graphite	C	1.0 to 2.0	2.1 to 2.2
Gypsum	$CaSO_4.2H_2O$	1.5 to 2.0	2.3
Hematite	Fe_2O_3	5.5 to 6.5	4.9 to 5.3
Hypersthene	$(MgFe)SiO_3$	5.0 to 6.0	3.4 to 3.5
Kaolinite	$H_4Al_2Si_2O_9$	2.0 to 2.5	2.6
Lepidolite	$(KLi)_3Al(SiO_3)_3$	2.0 to 2.5	2.0 to 3.2
Leucite	$KAl(SiO_3)_2$	5.5 to 6.0	2.4 to 2.5
Magnesite	$MgCO_3$	3.5 to 4.5	3.0 to 3.12
Magnetite	Fe_3O_4	5.5 to 6.5	4.9 to 5.2
Malachite	$Cu_2(OH)_2CO_3$	3.5 to 4.0	3.9 to 4.0
Microcline	$KAlSi_3O_8$	6.0 to 6.5	2.5 to 2.6
Nephelite (Elaeolite)	$(NaK)_8Al_8Si_9O_{34}$	5.5 to 6.0	2.5 to 2.6
Orthoclase	$KAlSi_3O_8$	6.0 to 6.5	2.4 to 2.6
Plagioclase	$nNaAlSi_3O_8 + mCaAl_2Si_2O_8$	5.0 to 7.0	2.6 to 2.7
Pyrite	FeS_2	6.0 to 6.5	4.9 to 5.2
Pyrolusite	MnO_2	1.0 to 2.5	4.7 to 4.86
Pyroxene	$RSiO_3$	5.0 to 6.0	3.2 to 3.6
Pyrrhotite	FeS	3.5 to 4.5	4.5 to 4.6
Quartz	SiO_2	7.0	2.6
Serpentine	$H_4Mg_3Si_2O_9$	2.5 to 4.0	2.5 to 2.65
Siderite	$FeCO_3$	3.5 to 4.0	3.8 to 3.9
Talc	$H_2Mg_3(SiO_3)_4$	1.0 to 1.5	2.5 to 2.9

* From "A Guide to the Sight Recognition of 120 Common or Important Minerals," by A. J. Moses in Farrell, "Practical Field Geology," McGraw-Hill.

Clay schist is composed of hardened clay and quartz, often with little lamellae of mica. It cleaves readily and is therefore suitable for roofing. See also Slate, p. 724.

Limestone (carbonate of lime), if capable of taking high polish, is called **marble.** The color varies with amounts of iron oxide, copper oxide, etc. By ignition, it produces **caustic lime. Calcite** is transparent and used as sculptor's marble. **Chalk,** another form of limestone, is white and earthy.

Marl is a dense, earthy or slaty rock, consisting of a mass of carbonate of lime mixed with clay and siliceous sand. Certain species are well suited for the manufacture of cement.

Dolomite, a magnesian carbonate of lime, is whitish-yellow or gray to brown in color, crystallized and dense. Certain deposits produce a hard durable building stone, well suited for road building.

Gypsum, hydrated sulphate of lime, is generally white, but often yellowish to reddish, or gray to blackish; it is not durable when exposed to weather.

Sandstone consists of sand grains made up into a more or less compact rock by a binder consisting generally of silicon, lime, or clay. It often contains calcite, mica, iron ore, and admixtures of red and green clay. Iron pyrites has a disintegrating effect; an abundance of mica is also undesirable.

Artificial graphite is made by the International Acheson Graphite Co., of Niagara Falls. Amorphous carbon is converted to graphite by subjecting carbonaceous material to a temperature in the electric furnace above the volatilization point of impurities such as iron and silicon. It is possible to produce absolutely pure graphite in this manner. Its principal use at present is in the manufacture of electrodes. Large amounts are sold as a lubricant after a special treatment called "deflocculation," which makes possible its colloidal suspension in water or oil. **Aquadag** and **oildag** are products of this kind containing deflocculated graphite in water and oil, respectively.

Graphite for foundry use is often called **plumbago**, as it was originally supposed that graphite was a form of black lead. The U. S. Navy specifies *that plumbago shall be dry, free from coal dust or grit,* and shall *contain* not less than 55 percent of graphite carbon.

Graphite refractory brick are used for furnace linings on account of their great heat-resisting qualities. The product known as **kryptol**—composed of graphite, carborundum, and clay—is used for electric resistance furnaces as its resistance is sufficient to localize a high degree of heat without the material itself being destroyed.

HEAT INSULATORS

REFERENCES: "Asbestos, Its Origin and Production," *Chemical World*, Jan., 1913. Printed matter issued by the H. W. Johns-Manville Co., Armstrong Cork Co., Celite Products Co., and American Balsa Co. Symposium on Thermal Insulating Materials, A.S.T.M., 1939. Thomas, "Cork Insulation," Nickerson & Collins. Dalzell and McKinney, "Air-conditioning Insulation," Am. Tech. Soc., 1937.

Chemical composition is no index of insulating value. For example, the conductivity of solid graphite is more than two hundred times as great as that of the same material in finely powdered form. The composition of the material should be suited to the service required of it, but the insulating value is determined by the **physical structure** which should be such that the optimum number of surface resistances are interposed in the path of heat flow.

Powdered or Fibrous Insulating Materials. Mineral wool, powdered gypsum, graphite, charcoal, shavings, sawdust, diatomaceous earth, basic *magnesium carbonate, asbestos, cork-dust, wool fiber.*

Molded Insulators. Powdered cork may be molded into corkboard by heat and pressure. Some powdered and fibrous insulating materials may be molded with water and afterward dried. In other cases, a binder must be used, such as waterglass, clay, or asphalt. The presence of even a small amount of binder decreases the insulating quality of the material very considerably.

Flexible insulations are usually made by stitching fibrous material between layers of kraft paper. Common fillers are eel grass, wood fiber, flax tow, kapok, jute, and hair.

Cast Insulations. Insulex and **pyrocel** are gypsum materials, cast in place, leaving a cellular structure. Porous concrete has also been made, using crushed ice or cinders instead of gravel.

Sprayed Insulation. Spray-o-flake is paper scrap mixed with water glass and asphalt. Thickness can be built up by spraying to 2 in.

Air. Commercial insulators owe their insulating value to the spaces or voids in their structure and not to the air itself. The best insulation is the one

Definitions of Paper," Lockwood. "Dictionary of Paper," Am. Paper & Pulp Assn., 1940. Clapperton and Henderson, "Modern Papermaking," Blackwell. Jahans, "Paper Testing and Chemistry for Printers," Pitman. Sutermeister, "Chemistry of Pulp and Papermaking," Wiley.

Paper is a matted or felted structure of fibrous material formed into a relatively thin sheet through the medium of a dilute suspension of pulp and water, and composed essentially of cellulose fibers obtained from vegetable growths in a more or less pure state.

Pulp for papermaking is prepared by grinding wood mechanically, by cooking chemically according to either of the three standard cooking processes, *i.e.*, sulphite, kraft, or soda, and also by chemically treating cotton, linen, and hemp rags, waste, esparto, straw, etc. So-called semichemical pulp processes, involving only partial disintegration of the wood structure, have been introduced lately. By these methods, wood wastes, such as sawmill refuse, which are usually burned as fuel, can be worked into cheap boards. The use of rags is at present confined to only the most particular grades of papers, as, for example, the highest grades of bond and writing, condenser papers, etc.

The lower grades of paper, such as **newspaper**, are made largely from groundwood mixed with a certain percentage of chemically prepared pulp. **Book paper** is made from a mixture of sulphite and soda pulp, with the addition of varying amounts of fillers such as clay and talc. These are added to improve the surface and printing qualities so necessary in this grade. **Insulating paper** for use in cable winding, while formerly made from all high-grade manila stock, is at present being made almost entirely from kraft. **Kraft** is now used to make practically all twisting and wrapping papers.

Box boards, container boards, Bristols, etc. are made from ground wood and chemically prepared pulp, such as sulphite or kraft, or mixtures of these, and waste papers. Thick, lightweight, insulating boards for building construction are made from waste materials such as bagasse and newspapers, licorice root, groundwood, and sulphite screenings.

In testing papers, **tensile strength** (500 to 2,500 lb per sq in.), stretch, and bursting are of importance; tests should be made on special machines. Comparison of different samples of the same grade of paper can be roughly made by tearing, crumpling and by visual examination for freedom of dirt and other indications of careless manufacture.

ROOFING MATERIALS

(Material Furnished by Bird & Son, East Walpole, Mass.)

REFERENCES: Abraham, "Asphalts and Allied Substances," Van Nostrand. A.S.T.M. Tentative Standards. Grondal, "Certigrade Handbook of Red Cedar Shingles," Red Cedar Shingle Bureau, Seattle, Wash.

Asphalt. Asphalts are bitumens, and the one most commonly seen in roofing and paving is obtained from petroleum residuals. Lake asphalts such as Trinidad and Bermudez, are used primarily in paving. Natural asphalts such as **Gilsonite** and **Elaterite** are too hard and brittle for use in roofing or paving, but are used extensively in asphalt coating, paints, and varnishes.

Petroleum residuals are obtained by the refining of petroleum. The qualities of asphalt are affected by the nature of the crude and the process of refining. Mid-Continent, Mexican, Venezuelan, Texan; and certain Californian asphalts are very satisfactory. When the flux asphalts obtained from the oil refineries are treated by blowing air through them while the asphalt is maintained at a high temperature, a material is produced which is very stable and has good weathering properties.

this type of material are **kieselguhr, diatomaceous earth, infusorial earth, Sil-O-Cel,** and **celite.** Material from the better deposits is almost pure silica which fact accounts for its high heat resistance. Where the material has been contaminated with clay, lime, sand, and other foreign matter, the density is increased and the insulating value and heat resistance are decreased. Insulating bricks are sawed directly from the material in the better deposits, for use at temperatures up to 1600 F.

Uses. Calcined bricks are made for temperatures as high as 2500 F. The material is also used in powdered form as an insulating fill and is mixed with asbestos fiber and bonding material for the production of moulded blocks and pipes insulation for use at temperatures up to 1600 F. Calcined granular material is used as an insulating fill at higher temperatures and is mixed with Portland cement to provide semirefractory insulating concrete for furnace doors, furnace foundations, the fireproofing of steel members, etc.

Other uses of diatomaceous silica are in the manufacture of a clarifying agent for use in filtering, as an admixture to improve the workability of concrete, stucco, and mortar, as a lightweight mineral filler for use in compounds such as polishes, paints, varnishes, enamels, lacquers, insecticides, matches, linoleum, catalysts, dynamite, etc.

Asbestos is a heat-resisting fibrous mineral, the most important deposits of which are in Canada. The **chrysotile variety,** because of its fineness of fiber, tensile strength, elasticity, and flexibility, is commercially the most important and references to asbestos without other designation presumably indicate this variety. Other useful varieties are Amosite or Rhodesian asbestos and blue or Cape asbestos, both from South Africa. The amphibole or hornblende variety is of little commercial value because of its brittleness and lack of fiber strength.

Uses. High-quality asbestos because of its incombustibility, its low heat and electrical conductivity, and its resistance to the action of most chemical agents has a wide variety of uses among which are heat and electrical insulations, packings and gaskets for high-temperature service, brake linings and friction materials, cloth for theater curtains, and heat-protective clothing, roofings, and building materials. It is spun and woven into yarn, rope, and cloth, is formed into asbestos felt, paper, roll board, and mill board for insulation, is mixed with Portland cement to make fireproof shingles and asbestos wood, and it constitutes either the principal ingredient or the essential reinforcing material for most insulations in the range of temperatures from 150 to 1600 F. Among the insulations consisting principally of asbestos are laminated-felt types made up of successive layers of thin felts, the felted fiber types (asbestos fiber and bonding material) and the air cell types made up of successive layers of plain and corrugated asbestos paper.

It has an approximate **dielectric strength** of 4,000 volts per mm and a specific resistance of 16×10^4. Good asbestos should not burn or show any flame under the blowpipe nor should it be affected by concentrated hydrochloric acid. Asbestos wood is obtainable in standard sheets 36 × 48 in., and in thicknesses from ⅛ in. by ⅛ in. to 1 in., and then by ¼ in. increases to 2 in.

The **U. S. Navy specifications** call for **asbestos millboard** in standard sheets 40 × 40 in., the various thicknesses to have the following weights: ½ in., 25 to 29 lb; ⅜ in. 21 to 24 lb; ¼ in., 14 to 16 lb; 3/16 in., 11 to 12 lb; ⅛ in., 7 to 8 lb; 1/16 in., 3½ to 4½ lb. Asbestos millboard is generally made hard, but, if desired, can be made medium or soft. The material should stand a dry heat of 400 F without injury and should not be affected by acids.

The U. S. Navy specifies for **asbestos plaster for pipe covering** a mixture of 5 percent of long asbestos fiber, 65 percent of infusorial earth (see above) and 30 percent of fireproof binding material. The material must mix with water to proper consistency, and, after drying, should not burn or show any flame. It should not bake hard like a brick but be capable of compression. One bag, 140 lb net weight, should cover 40 sq ft of surface 1 in. thick.

Gulf States is preferable. Redwood shingles come 5½ butts to 2 in.; lesser thicknesses are more liable to crack and have shorter life. Shingles 8 in. wide or over should be split before laying. Dimension shingles of uniform width are obtainable. Dipping in oil or creosote adds to life. Creosote stains are both preservative and decorative. Shingles should be dipped before laying for best results. Wood shingles make a lasting roof, but materially increase the fire hazard.

Slate should be hard and tough and have a well-defined vein that is not too coarse. If too soft, they will absorb water; if too brittle, they are easily broken on cutting and installing. The surface when freshly split should have a bright metallic luster, be free from loose flakes or dull surfaces, and be straight and true. Slate should give a clear metallic ring when struck. Color is not an indication of quality. Black ribbon slate is cheaper than all-black slate and equally good if appearance is unimportant. The color of slate varies from dark blue, bluish black, and purple to gray and green. Stock sizes range from 7 × 9 in. to 14 × 24 in.; thickness, from ⅛ to ⅜ in., $^{3}/_{16}$ in. being the usual thickness. Approximate weight varies from 650 to 850 lb per square. Slate roofs rank well in regard to fire hazard but are not so good as tile on exposure to adjacent conflagrations.

Metallic roofings are laid in large sheets without sheathing (often strengthened by corrugating), sometimes cut into small sizes and laid as shingles, bent into interlocking shapes like tile, or soldered into a single structure as in tin roofing. Metal tile and metal shingles are usually made of copper, copper-bearing galvanized steel, tin plate, or zinc. The lightest weight metal shingle is the one made from copper which weighs from 72 to 118 lb per square. The metal radiates the heat resulting in lower temperatures beneath these roofs than with most other types of uninsulated roofs.

Tile. Hard-burned clay tiles with overlapping or interlocking edges cost about the same as slate. They should have a durable glaze and be well made. Unvitrified tiles with *slip* glaze are satisfactory in warm climates, but vitrified tiles only should be used in the North. Tile roofs weigh from 750 to 1,200 lb per square. Properly made tile does not deteriorate, is a poor conductor of heat and cold, and is not so brittle as slate.

Asbestos shingles and sidings are composed of Portland cement reinforced with asbestos fiber and formed under great pressure. They resist the destructive effect of time, weather, and fire. Asbestos shingles—American method—weigh about 500 lb per square and carry Underwriter's Class A label. Dutch lap and hexagonal or French method asbestos shingles weigh 250 to 300 lb per square and carry the Underwriter's B label. Asbestos shingles are made in a variety of colors and shapes. The asbestos roofing shingles have a smooth surface or a textured surface which represents wood graining.

Asbestos siding is commonly made in 12 × 24 in. strips and applied with a 10½ × 24 in. exposure. Such siding weighs about 200 lb per square and is produced in white, gray, and colors.

RUBBER, GUTTA PERCHA, AND BALATA

REFERENCES: Bedford and Winkelman, "Survey of Rubber Chemistry," Reinhold. Davis and Blake, "Chemistry and Technology of Rubber," Reinhold. Geer, "Rubber Compounding 1918–1938," Chemical Industries, vol. 42, p. 640, 1938. Hauser, "Latex," Reinhold. Schidrowitz, "Rubber," Van Nostrand. Whitby, "Plantation Rubber and the Testing of Rubber," Longmans.

These three substances, which are frequently confused, are all produced by the coagulation of the latex from certain shrubs and trees and are similar

of various sorts rendered absorptive by the addition of powdered chalk or whiting and after being molded into form covered with a glazing solution composed of starch, gelatin and turpentine; and **leatheroid**, a combination of chemically treated paper with rubber and sandarac, often used for trunks and suitcases.

NATURAL STONES

REFERENCE: Baker, "Masonry Construction," Wiley.

The important **qualities** in stone for building construction are cheapness, durability, and strength. Stones are seriously affected by weather, chemicals, gases, and temperature. Resistance to weathering depends upon both the hardness and the absorbent properties of the stone. Porosity is an objectionable element. If the constituents differ greatly in characteristics, weathering is apt to be unequal, consequently starting disintegration.

In general, crystalline structure is more durable than amorphous. Examination of the condition of the stone in the quarry affords some idea as to its durability. Further information can be obtained by artificial tests of weight, crushing strength, absorption, and resistance to freezing, to acids, and to heat.

The **structure** of the stone is of prime importance where heavy loads are to be carried. All stones are classified on the basis of the mineral forming the chief constituent, *viz.*, **siliceous stones**, such as granite, syenite, gneiss, trap, and quartz; **argillaceous or clayey stones**, in which alumina is the predominating mineral, such as slate; **calcareous stones** in which carbonate of lime predominates, such as limestone, marble, and dolomite. From a practical standpoint, stones are also divided into two classes—**stratified** and **unstratified**—the former being represented by such stones as marble, slate, etc., whereas the **unstratified** stones consist of an aggregate of crystalline grains such as granite, trap, and basalt lava.

The table on p. 720 gives the composition and some of the properties of the more common minerals.

Granite, composed of feldspar, quartz, and mica, is the strongest and most durable of stones in common use and is quarried into shape with facility. It is extremely hard and tough and can be wrought into elaborate shapes only with great difficulty. The feldspar content determines the coloring, while the quartz determines essentially the hardness.

Trap is a very strong and durable stone, but quarried and wrought with great difficulty. It is exceedingly tough and is widely used for roads and railroad ballast.

Syenite, composed of feldspar and hornblende, is crystalline, granular, and speckled black and white; it is hard, and takes a good polish. **Diorite** and **diabase** are similar stones and are frequently known as **greenstone**.

Serpentine is generally green in color and disintegrates in the open air. Soapstones and asbestos are related to it.

Trachytes are dense, frequently porous, feldspathic rocks with admixtures of crystals of hornblende, biotite, and magnetite. They are gray in color. Pumice stone is a variety.

Augitites. Basalt, a solidified product of volcanic emission, is a common variety, and the most durable and pressure-resisting structural stone; it is valuable for road-building and for bank and supporting walls. **Basalt lava** is very porous rock varying in color and hardness, used for stairs, paving blocks, and millstones.

Gneiss, a schistose structure of granite, is more subject to decomposition than granite, especially if rich in feldspar and mica.

Quartzite (pure or almost pure quartz) is characterized by its vitreous crystallization. When porous, it is used for millstones; it is also used in the manufacture of glass, and as broken stones or as gravel in road building, for preparing concrete, etc.

Mica schist consists of gray quartz between layers of mica. It is used for roofing plates.

To soften (for purposes of manipulation or for final properties): bituminous bodies such as the so-called "mineral rubbers," coal tar, wood tar, and their products, various vegetable and mineral oils, paraffin and petrolatum, sulphurized and sulphur chlorinated oils.

Vulcanization accessories, dispersion and wetting mediums, etc.: magnesium oxide zinc oxide, litharge, lime, stearic and other organic acids, degras, pine tars.

Coloring pigments: iron oxides, especially the red grades, zinc oxide, lithopone, titanium compounds, chromium oxide, ultramarine blues, carbon and lampblacks, antimony sulphides, etc., and organic pigments of various shades.

Specifications should state the percentage and kind of rubber desired, the specific gravity of compound, and suitable physical tests. Tensile strength and stretch tests are of importance, but vary widely with different compounds. A good 30 percent para compound should have a tensile strength of at least 1,000 lb per sq in. and should stretch to at least 5 times its length before breaking. A piece stretched to 3 times its length should show a permanent elongation of not more than 20 percent. High-grade sheet rubber shows a tensile strength of 2,700 lb per sq in., an ultimate elongation of over 600 percent, and a set of about 10 percent measured after 300 percent elongation for 1 min with 1 min rest. Lower grades show lower strength and elongation but greater set. The treads of the better grades of tires have a tensile strength of about 4,000 lb per sq in. Rubber compounds with a strength of even 5,000 lb per sq in. have been produced. Chemical analysis is of value in detecting rubber substitutes, reclaimed rubber, and foreign substances, but, generally speaking, does not serve to identify the grade of rubber. Rubber for permanent use should be slightly undervulcanized rather than overvulcanized. Rubber compounds are extensively used for electrical insulation, hose, steam and water packing, buffers, tiling, and numerous other purposes where electrical strength, resilience, and waterproofing qualities are desired.

Latex. The use of preserved latex has extended the use of rubber, improving old products and permitting the production of valuable new products. A striking new product is **vulcanized latex,** the invention of Schidrowitz. This latex retains its creamy fluidity and in spite of the fact that the particles of rubber are vulcanized, the liquid dries, by evaporation of the water, to give a strong, tough, and coherent film. The use of this latex permits the application of rubber to materials which are too sensitive to withstand the physical and chemical manipulation of the usual rubber factory.

Hard rubber, also known as **ebonite** and vulcanite, is made by vulcanizing rubber with a large quantity of sulphur and for a considerable time. It can be softened by heat and then be shaped or molded as desired, is capable of being highly polished when free from mineral admixtures, does not oxidize readily, and is not affected by air and sunlight, is very impervious to electricity but becomes charged with static electricity when rubbed. The substance is brown to black and resembles horn in appearance. The solvents that dissolve raw rubber and partly dissolve vulcanized rubber have no influence on hard rubber. It offers great resistance to all acids. If exposed for a long time to temperatures above 400 F, it does not melt but carbonizes. It is extensively used for switch handles, for covering tools for electrical purposes, insulating tubes for electrical conduits, fountain-pen handles, linings for acid vats, and numerous other purposes. Its use is being somewhat superseded by synthetic resinous plastics.

A **semihard rubber** is also made by varying the degree of vulcanization. This is more flexible and elastic than hard rubber and more durable than ordinary vulcanized rubber.

Reclaimed rubber is chiefly used as a cheap source of rubber hydrocarbon. A better product can be made at a low price by the use of reclaimed rubber than by the overloading of crude rubber with mineral fillers. In addition, reclaimed rubber is employed for its own specific properties. It is insoluble in the solvents of crude rubber, and its use is thus indicated where rubber comes into contact with oils, gasoline, etc. It may act as a dispersing medium, accelerates vulcanization, and often imparts manipu-

Conglomerates consist of rounded pebble stones formed by the aggregation of various rocks, held together by a binder such as clay or marl.

Gravel and **sand** consist of small fragments of quartzy minerals, often mixed with lime, marl, and clay, from which they can be liberated by washing. Pit sand is ordinarily gritty but frequently more impure than river sand.

Clay is a hydrous silicate of aluminum; as it occurs in nature it is frequently a mixture of clay with sand, limestone, and oxide of iron produced by the erosion of rocks containing feldspar minerals. The purest variety, **kaolin**, is used for the production of chinaware, and as a papermaking material. Plastic varieties are used for pipe clays, fireproof clays, and potter's clays. Clay shrinks in drying and subsequently in burning without losing its form as a whole, and becomes extremely hard. Certain varieties known as **fuller's earth** are very absorbent of oils or dyes. See also Brick, p. 700.

For strength and other physical properties of natural stones, see Table 3, p. 419.

PAINT OIL

(See also p. 674)

China wood oil (tung oil), expressed from the tung nut, is being increasingly used as a substitute for linseed oil in paints and varnishes. It has a peculiar rancid odor and yellow color, usually darker than that of linseed oil. It has the unique property of apparently drying throughout at a uniform rate when spread in a film instead of forming a skin by surface drying as does linseed oil. It dries "flat" instead of glossy, with an opaque, white film. When heated to about 400 F, it is converted into a jellylike mass insoluble in ordinary solvents. Specific gravity, from 0.936 to 0.944; its other constants are very similar to those of linseed oil. It can be mixed with lead and manganese driers. Its peculiar drying properties and resistance to water when dry have been successfully utilized in varnish making. It costs more than linseed oil.

Linseed oil is a brownish-yellow vegetable oil with a specific gravity between 0.931 and 0.937. It possesses the property of absorbing oxygen and consequently drying to a greater extent than most other oils; hence largely used for paints and varnishes. It is frequently adulterated with cottonseed, rosin, fish, mineral, and soybean oils. **Adulteration** can sometimes be detected by odor, color, or gravity, but chemical analysis is usually necessary. Mixtures of China wood, soybean, and linseed oils can be made which are extremely difficult to detect. Adulteration with mineral or rosin oil can frequently be detected by a green or blue fluorescence which appears when the oil is viewed on a black background with the back to the light.

As raw oil dries very slowly, it is frequently used as **"boiled oil."** The name was derived from the original practice of boiling the oil in open kettles at a temperature of 300 to 500 F and incorporating oxides of lead and manganese, this process greatly increasing the drying properties. Little if any boiled oil is now made in this way, as the original process was expensive and darkened the oil greatly. So-called "boiled oil" is now made by heating a small quantity of oil with lead and manganese oxides and subsequently adding this drier to the raw oil. A third class, known as **bunghole oil**, is made by adding driers dissolved in benzine or turpentine to the raw oil. If properly made the quicker processes produce satisfactory oil. Boiled oil should have a similar odor and taste to raw oil; specific gravity, between 0.931 and 0.950.

Perilla oil; treated **fish oil, soybean oil,** and **oiticica oil** are prominent among the newer oils used in paints and varnishes, generally in conjunction with some synthetic resins.

REFRACTORIES

BY

F. H. NORTON

REFERENCES: Buell, "The Open-hearth Furnace," 3 vols., Penton. Bulletin R-2-E Babcock and Wilcox Co. "Modern Refractory Practice," by Harbison Walker Refractories Co. Norton, "Refractories," McGraw-Hill. A.S.T.M. Standards on Refractory Materials (Comm. C-8). Trinks, "Industrial Furnaces," vol. I. Wiley. Scholes, "Modern Glass Practice," Industrial Publications, Inc.

Types of Refractories

Fire-clay Refractories. Fire-clay brick are made from fire clays, which comprise all refractory clays that are not white burning. Fire clays can be divided into plastic clays and hard flint clays; they may also be classified as to alumina content.

Firebricks are usually made of a blended mixture of flint clays and plastic clays which is then formed, after mixing with water, to the required shape. Some or all of the flint clay may be replaced by highly burned or calcined clay, called **grog**. A large proportion of the modern bricks is molded by the dry-press or power-press process where the forming is carried out under high pressure and with a low water content. Extruded and hand-molded brick are still made in large quantities.

The dried bricks are burned either in periodic or tunnel kilns at temperatures varying between 2200 and 2600 F. Tunnel kilns give continuous production and a uniform temperature of burning.

Fire-clay bricks are divided into grades according to the A.S.T.M. designation: *Low-heat-duty brick*, fusion point above 2770 F (cone 19). *Moderate-heat-duty brick*, fusion point above 2905 F (cone 26). *Intermediate-heat-duty brick*, fusion point above 2940 F (cone 28). *High-heat-duty brick*, fusion point above 3055 F (cone 31). *Superduty fire-clay brick*, fusion point above 3171 F (cone 33).

Fire-clay bricks are used for boiler settings, kilns, malleable-iron furnaces, incinerators, and many portions of steel and non-ferrous metal furnaces. They are resistant to spalling and stand up well under many slag conditions, but are not generally suitable for use with high-lime slags, fluid-coal-ash slags, or under severe load conditions.

High-alumina brick are manufactured from raw materials rich in alumina, such as diaspore. They are graded into groups with 50, 60, 70, 80, and 90 percent alumina content. When well fired, these brick contain a large amount of mullite and less of the glassy phase than is present in the firebricks. Corundum is also present in many of these bricks. High-alumina brick are generally used for unusually severe temperature or load conditions. They are employed extensively in limekilns and rotary cement kilns, the ports and regenerators of glass tanks and for slag resistance in some metallurgical furnaces; their price is higher than firebrick.

Silica brick are manufactured from crushed ganister rock containing about 97 to 98 percent silica. A bond consisting of 2 percent lime is used, and the bricks are fired in periodic kilns at temperatures of 2700 to 2800 F for several days until a stable volume is obtained. They are especially valuable where a good strength is required at high temperatures.

Silica brick are used extensively in coke ovens, the roofs and walls of open-hearth furnaces, in the roofs and side walls of glass tanks, and as linings of

Coal Tar. Coal tar is more susceptible to temperature change than asphalt, and therefore for roofing purposes its use is usually confined to flat decks. Coal-tar built-up roofs are used extensively.

Asphalt prepared roofing is manufactured by impregnating a dry roofing felt with a hot asphaltic saturant. A coating consisting of a harder asphalt compounded with a fine mineral filler is applied to the weather side of the saturated felt. Into this coating is embedded mineral surfacing such as mineral granules, powdered talc, mica, or soapstone. The reverse side of the roofing has a very thin coating of the same asphalt which is usually covered with powdered talc or mica to prevent the roofing from sticking in the package. The surfacing used on **smooth-surfaced roll roofing** is usually powdered talc or mica. The surfacing used on **mineral or slate-surfaced roll roofing** is roofing granules in either natural colors prepared from slate or artificial colors usually made by applying a coating to a rock granule base. **Asphalt shingles** usually have a granular surfacing. They are made in strips and as individual shingles. The different shapes and sizes of these shingles provide single, double, and triple coverage of the roof deck.

Materials Used in Asphalt Prepared Roofing. The felt is usually composed of a continuous sheet of felted vegetable and animal fibers. High-grade roofing felts contain usually about 50 to 70 percent cotton, 10 to 20 percent wool, and 5 to 20 percent jute, manila, and wood fibers. The constituents can be varied to give felts with varying absorptive capacities.

The most satisfactory roofing **asphalts** are obtained by air blowing a steam- or vacuum-refined petroleum residual. Saturating asphalts must possess a low viscosity in order for the felt to become thoroughly impregnated. Coating asphalts must have good weather-resisting qualities and possess a high fusion temperature in order that there will be no flowing of the asphalt after the application to the roof. The coating asphalt is blown for a much longer time than is the saturating asphalt. It has been found that the addition of 30 to 40 percent of a finely ground mineral filler to the coating asphalt greatly improves its weathering qualities.

The fine **mineral surfacings** used on smooth-surfaced roll roofings are mica, talc, or soapstone. The coarse grade of mineral surfacing which is used on slate-surfaced roll roofing and asphalt shingles is either a crushed slate or rock. The coarse mineral granules are often colored artificially by coating them with pigmented silicate, cement, or a ceramic glaze and firing the granules to such a temperature that the coatings are permanent.

Asphalt built-up roofing usually consists of several layers of asphalt saturated felt with a continuous layer of hot mopped asphalt between the layers of felt. The top layer of such a roof may consist of a hot mopping of asphalt with slag or gravel embedded therein or a slate-surfaced cap sheet. Asphalt built-up roofs are never applied to an absolutely flat or dead level deck; the pitch must be from ¼ to 6 in. per ft.

Coal-tar built-up roofs are similar in construction to the asphalt built-up roofs. Several layers of tar saturated felt have a continuous layer of hot mopped pitch between each layer of felt. The tar built-up roofs usually have a top surfacing of slag or gravel. As coal tar is more susceptible to temperature change than asphalt, it is used only when the pitch is less than 2 in. per ft. Asphalt or asphalt-saturated felts should not be applied on the same deck with pitch or tar-saturated felts.

Wood Shingles. Wood shingles are usually manufactured in three different lengths: 16, 18, and 24 in. There are three grades in each length, the No. 1 grade being the best and the No. 3 grade being intended for purposes where the presence of defects will not be objectionable. See p. 684.

Clear white-pine shingles are the best. Red-cedar shingles of good quality are obtainable from the Pacific Coast. In the South, red cypress from the

of severe temperature and heavy load, or severe spalling conditions, as in the case of high-temperature oil-fired boiler settings, or piers under enameling furnaces. This type of brick has also been found of considerable value in the upper structure of glass tanks and checkers. Another brick for the same uses is a high-fired brick of Missouri aluminous clay.

There are a number of bricks on the market made from electrically fused materials, such as fused **mullite**, fused alumina, and fused **magnesite**. These bricks although high in cost are particularly suitable for certain severe conditions.

Bricks of **silicon carbide** (see p. 695), either recrystallized or clay bonded, have a high thermal conductivity and find use in muffle walls and as a slag-resisting material.

Other types of refractory that find certain limited use are **forsterite, zirconia,** and **zircon.** Acid-resisting brick consisting of a dense body like stoneware are used for lining tanks and conduits in the chemical industry.

Natural stones such as sandstone or mica schist are used as refractories in metallurgical furnaces such as the linings of Bessemer converters. Soapstone is used in soda and sulphate recovery furnaces, but is being replaced to some extent by chrome.

The **chemical composition** of some of the refractories is given in Table 1. The **physical properties** are given in Table 2. Reference should be made to A.S.T.M. standards for details of standard tests.

Table 1. Chemical Composition of Typical Refractories[a]

No.	Refractory type	SiO_2	Al_2O_3	Fe_2O_3	TiO_2	CaO	MgO	Cr_2O_3	SiC	Alkalies	Resistance to: Siliceous steel-slag	High-lime steel-slag	Fused mill-scale	Coal-ash slag
1	Alumina (fused)	8-10	85-90	1-1.5	1.5-2.7					0.8-1.3[c]	E	G	F	G

in many respects. The essential difference between gutta percha and rubber is that the former becomes markedly soft and plastic on immersion in hot water, retaining any shape then given to it on cooling, whereupon it becomes hard but not brittle like other gums. Rubber or caoutchouc, on the other hand, does not soften materially in hot water and retains its original elasticity and strength almost unimpaired. Balata behaves on heating very much the same as gutta percha but possesses very little elasticity. It can be vulcanized, but without improved properties, whereas rubber and gutta percha are readily vulcanized and possess different properties after vulcanization.

Rubber is obtained principally from the far East—from the cultivated plantations of Ceylon, the Malay Peninsula, the Straits Settlement, Java, Sumatra, etc. In addition, about 5 percent of the world's supply is obtained as wild rubber, the best of which is the well-known fine para from Brazil. The tropical sections of South America and Africa produce various grades of rubber which are of declining importance. The cultivated Guayule of Mexico and New Mexico furnishes excellent rubber, which may, in time, compete to some extent with Hevea rubber.

High-grade rubber will stretch to approximately 10 times its length and at this point will bear a load of 10 tons per sq in. It can be compressed to one-third its thickness thousands of times without injury. When vulcanized for elasticity, it behaves in some respects like other engineering materials up to a load of 30 percent of the breaking load and at an extension of one-half the maximum. From this point on, however, the resistance increases in greater proportion than the extension, and finally assumes a comparatively high value. Even when stretched almost to the point of rupture, it restores itself very nearly to its original dimensions on being released, and gradually recovers a part of the residual loss of form.

The dielectric constant at 1,000 cycles is 2.37 for purified rubber, 2.68 for soft vulcanized, and 2.82 for hard rubber. The specific gravities are 0.906, 0.923, and 1.173, respectively. The color of vulcanized rubber containing only rubber and sulphur is yellow to brown; mineral and other additions may vary the color nearly to black.

Freshly cut or torn raw rubber possesses the power of self-adhesion which practically disappears in vulcanized rubber. Cold water indefinitely preserves rubber, but if exposed to the air, and particularly to the sun, all rubber goods tend to become hard and brittle. Dry heat up to 120 F should have little deteriorating effect, but at temperatures of 360 to 400 F rubber begins to melt, loses its elasticity, and becomes sticky; at higher temperatures, it becomes entirely carbonized. Unvulcanized rubber is soluble in carbon bisulphide, benzine, petroleum ether, and turpentine, but only readily so directly after milling.

Rubber is seldom used alone industrially except for surgical tape, rubber cements, and other minor purposes. Most rubber is vulcanized, *i.e.*, made to combine with sulphur, or in the case of some thin goods, sulphur chloride. Vulcanization if properly carried out improves the tensile properties, eliminates tackiness, renders the rubber less susceptible to temperature changes, and makes it insoluble in all known solvents. It is impossible to dissolve vulcanized rubber unless it is first decomposed. Other ingredients are added for general effects as follows:

To increase tensile strength and resistance to abrasion: carbon black, zinc oxide, magnesium carbonate, glue, certain clays, as well as most of the organic vulcanization accelerators.

To cheapen and stiffen: whiting, barytes, soapstone, silica and silicates, stale flour, infusorial earth, clays, fibrous materials.

The variation of the specific heat of refractories with temperature is indicated in Table 3 which gives data from Bradshaw and Emery (*Trans. Ceram. Soc.* (England), 19, 84–92, 1919–'20.)

Table 3. Specific Heat of Refractories

Temperature, deg F	Mean specific heat, 77 to t deg F			
	Silica 1	Silica 2	Fireclay	Zircon
1112	0.225	0.223	0.225	0.137
1832	0.255	0.252	0.255	0.157
2192	0.252	0.255	0.254	0.167
2552	0.293	0.295	0.297	0.175

Heyn (*Mitt. konig. Materialprufungsamt*, Jahrg. 32, 1914 p. 185) gives the following data on the specific heat of magnesite bricks:

Temp, t deg F	200	400	600	800	1000	1500	2000	2500
Mean specific heat between 77 and t deg F	0.219	0.233	0.244	0.252	0.257	0.270	0.282	0.294

Wilson, Holdcroft, and Mellor (*Trans. Ceram. Soc.* (England), 12, 1912–1913, p. 279) give the following formula for the specific heat of fire-clay bricks:

Mean specific heat $= 0.192 + 0.000033t$, where t is in deg F.

Standard and Special Shapes

There are a large number of **standard refractory** shapes carried in stock by most manufacturers. The manufacturers' catalogues should be consulted in selecting these shapes, but the more common ones are shown in Table 4. These shapes have been standardized by the American Refractories Institute and by the Bureau of Simplification of the U.S. Department of Commerce.

Special shapes are more expensive than the standard refractories, and, as they are usually hand molded, will not be so dense or uniform in structure as the regular brick. When special shapes are necessary, they should be laid out as simply as possible and the maximum size should be kept down below 30 in. if possible. It is also desirable to make all special shapes with the vertical dimension as an even multiple of 2½ in. plus one joint so that they will bond in with the rest of the brickwork.

Mortars, Coatings, Plastics, Castables, and Ramming Mixtures

Practically all brickwork is laid up with some type of **mortar** to give a more stable structure and to seal the joints. This mortar may be ground fire clay or a specially prepared mortar containing grog to reduce the shrinkage. The bonding mortars may be divided into three general classes. The first are **air-setting mortars** which often contain silicate of soda to give a strong bond when dried or fired at comparatively low temperatures. Many of the air-setting mortars should not be used at extremely high temperatures because the fluxing action of the air-setting ingredient reduces the fusion point. The second class is called **heat-setting mortar** and requires temperatures of over 2000 F to produce a good bond. These mortars vary in vitrifying point, some producing a strong bond in the lower temperature ranges, and the others requiring very high temperatures to give good strength. The third classification comprises **special-base mortars** such as silica, magnesite,

lative properties which are difficult to obtain when crude rubber is the sole source of the rubber hydrocarbon.

Rubber Substitutes. This name has been applied to sulphurized or sulphurchlorinated oils which are compounding ingredients and in no way true substitutes for rubber.

Synthetic rubbers are now available of several chemical types. **Neoprene** is a *polymerized chloroprene* and differs from rubber structurally in that chlorine replaces the methyl group in the molecule. **Buna S** and **Buna N** are butadiene rubbers, combined with Styrene and acrylonitrile, respectively. **Butyl** rubber is a synthetic product (1940) made principally from the olefines from the cracking of petroleum, but containing a small proportion of diolefines. **Thiokol** is a rubberlike polymerized ethylene sulfide. *Each of these synthetic types offers one or more advantages over* natural rubber, such as resistance to oil, to oxidation, or to heat or light, and some of them are of great strength or resistance to wear.

Gutta Percha. Pure gutta percha is colorless, and, when cut thin, transparent. It is tasteless, inodorous, softens at 99 F, and can be molded readily at 195 F. If heated above 265 F, it melts to a colorless oil; it is not affected by cold and is very resistant to water. When exposed to air and sunlight, it rapidly deteriorates. It possesses excellent heat resistance, and the greatest electrical resistance of any plastic material.

Gutta percha is insoluble in most reagents, is slightly soluble in pure alcohol and partly dissolved by turpentine, olive oil, and benzine. The best solvents are carbon bisulphide and chloroform. It is very little affected by acids or alkalies. On account of its great electrical resistance, waterproof qualities, and permanency under water, it was largely used in the first transatlantic cables. *It is little used today except for the manufacture* of golf balls and minor uses.

Balata. *Raw balata is gray, brown, or whitish red and possesses little elasticity.* It is softer than gutta percha under ordinary temperatures, does not become so firm when cooled, is soluble in turpentine, benzene, and carbon bisulphide, but resistant to acid and alkalies. It can be readily molded at 125 F. On account of its great toughness and resistance to moisture and air, it was formerly used for the manufacture of rubber belts. Its present chief uses are for the covers of golf balls and as a heat-plastic adhesive for combining fabrics and mending tissue.

SHELLAC

The most commonly used shellac for pattern and varnish work is the T. N. grade, *which usually contains about 3 percent of rosin. A grade called* Garnet lac sells at about the same price as T. N. and is free from rosin or lac-wax.

Shellac is soluble in alcohol, hot aqueous solutions of sodium and potassium carbonates, caustic alkalies, borax, and acetic acid. Its specific resistance is approximately 9×10^9 megohms per cu cm; **specific inductive capacity**, about 2.74. It is slightly hygroscopic but not sufficiently so to impair its value as an electrical insulator. Shellac softens at 181 F, flows readily at 230 to 248 F, hardens again at 356 to 384 F and begins to carbonize at 446 F.

Shellac is used extensively as a sticker and insulator in the manufacture of electrical apparatus, for bonding abrasive wheels, and as a bond for a variety of molded goods. The most common **adulterant** is rosin, which makes the shellac brittle. A common test is to heat a piece of shellac with a lighted match until one corner is melted, then blow out the flame and attach the match to the piece of shellac and let the latter drop to the floor. If the shellac is of good quality and ordinarily free from adulteration, it will string out in a thin flexible thread from the height of a man's hand held as high as possible from the floor. It has been found that the addition of 5 percent of rosin increases the adhesiveness. **Bleached shellac** is used very largely in lacquers and has less adhesive strength than **orange shellac**. It is not completely soluble in alcohol and nearly always contains some chlorine. The ordinary spirit varnish is made by dissolving from 4½ to 9 lb of shellac in a gallon of alcohol. 4½ lb per gal makes 1½ gal of varnish and 9 lb per gal makes 2 gal of varnish.

acid electric steel furnaces. Although silica brick is readily spalled (cracked by a temperature change) below red heat, it is very stable if the temperature is kept above this range, and for this reason stands up well in regenerative furnaces. Any structure of silica brick should be heated up slowly to the working temperature; a large structure often requires two weeks or more to bring up.

Magnesite brick are made from crushed magnesium oxide which is produced by calcining raw magnesite rock to high temperatures. A rock containing several percent of iron oxide is preferable as this permits the rock to be fired at a lower temperature than if pure materials were used. Magnesite brick are generally fired at a comparatively high temperature in periodic or tunnel kilns, though large tonnages of unburned brick are now produced. The latter are made with special grain sizing and hydraulically pressed.

Magnesite brick are basic and are used wherever it is necessary to resist high-lime slags such as in the basic open-hearth furnace. They also find use in furnaces for the lead and copper refining industry. The hydraulically-pressed unburned brick find extensive use as linings for cement kilns. Magnesite brick are not so resistant to spalling as fire-clay brick.

Chrome brick are manufactured in much the same way as magnesite brick, but are made from natural chromite ore. Commercial ores always contain magnesia and alumina. Unburned hydraulically-pressed chrome brick are also made.

Chrome bricks are very resistant to all types of slag. They are used as separators between acid and basic refractories, also in soaking pits and floors of forging furnaces. The unburned hydraulically-pressed brick now find extensive use in the walls of the open-hearth furnace. Chrome bricks are used in sulphite-recovery furnaces and to some extent in the refining of nonferrous metals.

The insulating refractory is a class of recently developed bricks which consist of a highly porous fire clay or kaolin. They are light in weight (about ½ to ¼ that of fireclay), low in thermal conductivity, and yet sufficiently resistant to temperature to be used successfully on the hot side of the furnace wall, thus permitting thin walls of low thermal conductivity and low heat content. The low heat content is particularly valuable in saving fuel and time on heating up, allows rapid changes in temperature to be made, and permits rapid cooling. These bricks are made in a variety of ways, such as mixing organic matter with the clay and later burning it out to form pores; or a bubble structure can be incorporated in the clay-water mixture which is later preserved in the fired brick. The insulating refractories are classified into several groups according to the maximum temperature that they can withstand on the hot face; the ranges are, up to 1550, 1950, 2250, 2550, and above 2750 F for 2 percent linear shrinkage.

Insulating refractories are used mainly in the heat-treating industry for furnaces of the periodic type; the low heat content permits noteworthy fuel savings as compared with firebrick. They are also used extensively in stress-relieving furnaces, chemical-process furnaces, oil stills or heaters, and in the combustion chambers of domestic-oil-burner furnaces; they usually have a life equal to the heavy brick that they replace. They are particularly suitable for constructing experimental or laboratory furnaces because they can be cut or machined readily to any shape. They are not resistant to fluid slag.

There are a number of types of **special brick**, obtainable from individual manufacturers. High-burned kaolin refractories are particularly valuable under conditions

Solid walls built with standard 9 in. brick are made up in various ways; 9 in. walls with alternate header and stretcher courses; 13½ in. walls with alternate header and stretcher courses, or with four stretcher courses to one header course on the hot face, or with four header courses to one stretcher course on the hot face; 18 in. walls with alternate header and stretcher courses.

Table 7. Transmitted Heat Losses and Heat-storage Capacities of Wall Structures under Equilibrium Conditions

(Based on still air at 80 F)

[a] Much of this data has been taken from a table prepared by L. J. Trostel, *Chem. Met. Eng.*, Nov., 1938.
[b] Excellent if left above 1200 F.
[c] Oxidizing atmosphere.
[d] Up to .56 at red heat.

the shut-down period of the furnace. Where slag or abrasion is severe, brick with a dense structure is desirable. If spalling conditions are important, a brick with a more flexible structure is better, although there are cases where a very dense structure gives better spalling resistance than a more open one.

High-lime slag can be taken care of with magnesite, chrome, or high alumina brick; but if severe temperature fluctuations are encountered also, no brick will give long life. For coal-ash slag, dense fire-clay bricks give fairly good service if the temperature is not high. At the higher temperatures, a chrome-plastic or silicon-carbide refractory often proves successful. When the conditions are unusually severe, air- or water-cooled walls must be resorted to; the water-cooled stud-tube wall has been very successful in boiler furnaces.

With a general freedom from slag, it is often most economical to use an insulating refractory. Although this brick may cost more per unit, it allows thinner walls, so that the total construction cost may be no greater than the regular brick. The substitution of insulating refractory for heavy brick in periodic furnaces has sometimes halved the fuel consumption.

The stability of a refractory installation depends largely on the bricklaying. The total cost, in addition to the bricks, of laying brick varies with the type of construction, locality, and refractory; but a figure of $100 per thousand is a fair allowance on small jobs; on a large structure, such as an open-hearth furnace, where approximately 1,000,000 brick would be laid, the total cost in addition to the bricks might be somewhat less than $50 per thousand.

Table 8. Refractory Prices

(Per thousand, carload lots at destination)

	Approximate costs in 1939
Fire-clay brick	$48.00 F.W.
Superduty fire clay brick	$61.00 F.W.
High-alumina brick	(50%, $85) (60%; $105) (70%, $130) F.W.
Kaolin brick	$240 (with mortar) F.W.
Mullite brick	$500 F.W.
Magnesite brick	$335 F.W.
Chrome brick	$270 F.W.
Clay-bonded silicon-carbide brick	$1,050 F.F.
Fused-magnesite brick	$1,500 F.F.
Fused-alumina brick	$1,140 F.F.
Insulating fire brick	(1960 F, $78) (2250 F, $102) (2550 F, $124) D.P.
Finely-ground fire clay for laying high-heat duty fire clay brick, in sacks	$11.35 N.T.
Superduty fire clay, in sacks	$22.30 N.T.
High-alumina fire clay, in sacks	$47.50 N.T.
Silica fire clay (for laying silica brick), in sacks	$12.80 N.T.
Silica-base high-temperature bonding-mortar, carload lots (in drums)	$65.00 N.T.
Chrome-base high-temperature bonding-mortar, carload lots (in drums)	$75.00 N.T.

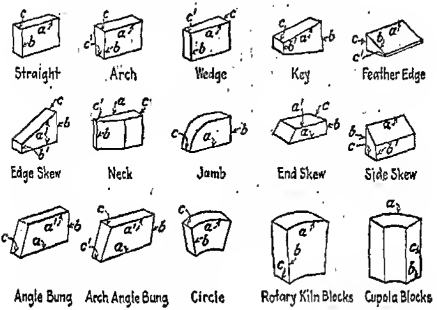
F.W. = F.O.B. works. F.F. = F.O.B. factory. D.P. = delivered in Pittsburgh. N.T. = net ton.

or chrome, which are specially blended for use with their respective bricks. The chrome-base mortar may be satisfactorily used with fire-clay bricks in many cases.

The refractory bonding mortars should preferably be selected on the advice of the manufacturer of the refractory to obtain good service, although there

Table 4. Sizes and Shapes of Firebrick

(All dimensions in in.)



Name of bricks	Straight bricks Length a	Width b	Thickness c	Name of bricks	Straight bricks Length a	Width b	Thickness c
9 in. straight.....	9	4½	2½	9 × 4½ × 3 in. straight........	9	4½	3
Small 9 in.......	9	3½	2½	9 × 6 × 3 in. straight.........	9	6	3
Soap............	9	2¼	2½	13½ in. straight..	13½	6	2½

Flat back straight	9	6	2½	Open-hearth checker........	10½	4½	4½

Regenerator tile sizes, $a \times b \times c$ are: 18 × 6 or 9 × 3; 18 × 9 or 12 × 4; 22½ × 6 or 9 × 3; 22½ × 9 or 12 × 4; 27 × 9 × 3; 27 × 9 or 12 × 4; 31½ × 12 × 4; 36 × 12 × 4.

The following **arch, wedge, and key bricks** have maximum dimensions, $a \times b \times c$ of 9 × 4½ × 2½ in. The minimum dimensions a', b', c' are as noted: No. 1 arch, $c' = 2\frac{1}{8}$; No. 2 arch, $c' = 1\frac{3}{4}$; No. 3 arch, $c' = 1$; No. 1 wedge, $c' = 1\frac{7}{8}$; No. 2 wedge, $c' = 1\frac{1}{2}$; No. 3 wedge, $c' = 2$; No. 1 key, $b' = 4$; No. 2 key, $b' = 3\frac{1}{2}$; No. 3 key, $b' = 3$; No. 4 key, $b' = 2\frac{1}{4}$; Edge skew, $b' = 1\frac{1}{2}$; Feather edge, $c' = \frac{1}{8}$; No. 1 neck, $a' = 3\frac{1}{2}$, $c' = \frac{5}{8}$; No. 2 neck, $a' = 2\frac{1}{2}$, $c = \frac{5}{8}$; No. 3 neck, $a' = 0$, $c' = \frac{5}{8}$; End skew, $a' = 6\frac{3}{4}$; Side skew, $b' = 2\frac{1}{4}$; Jamb brick, 9 × 2½; Bung arch, $c' = 2\frac{3}{8}$.

S.A.E. viscosity number	Saybolt viscosity range, sec at 130 F	S.A.E. viscosity number	Saybolt viscosity range, sec at 210 F
10	90–120	40	<80
20	120–185	50	80–105
30	185–255	60	105–125
40	>255	70	125–150

In the case of prediluted oils, S.A.E. Viscosity Numbers by which the oils are classified shall be determined by the viscosity of the undiluted oils.

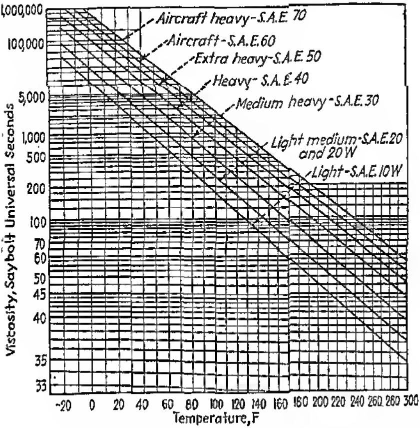

FIG. 1.—Variation of Viscosity with Temperature (A.S.T.M. D341-39 Viscosity Chart).

The S.A.E. viscosity numbers for transmission and rear axle lubricants constitute a classification in terms of viscosity and also of consistency at low temperatures. They are as follows:

S.A.E. viscosity number	Viscosity range, Saybolt Universal	Consistency. Must not channel in service at deg F
80	100,000 sec at 0 F, max.	Minus 20
90	800 to 1500 sec at 100 F	Zero
140	120 to 200 sec at 210 F	Plus 35
250	200 sec at 210 F, min.	....

are a considerable number of independent manufacturers of mortars who supply an excellent product. From 300 to 400 lb of dry mortar per thousand brick is required for thin joints, which are desirable in most furnace construction. For thicker trowel joints, up to 500 lb per thousand brick is required. In the case of chrome-base mortars, 600 lb per thousand brick should be allowed, and for magnesite cement 800 lb.

The working properties of the bonding mortar are important. Mortars for insulating refractories should be carefully selected as many of the commercial products do not retain their water sufficiently long to enable a good joint to be made. There are special mortars for this purpose which are entirely satisfactory.

Coatings are used to protect the hot surface of the refractories, especially when they are exposed to dust-laden gases or slags. These coatings usually consist of ground grog and fire clay of a somewhat coarser texture than the mortar. There are also chrome-base coatings which are quite resistant to slags, and in a few cases natural clays containing silica and feldspar are satisfactory.

The coatings can be applied to the surface of the brickwork with a brush in thin layers about $\frac{1}{16}$ in. thick, or they may be sprayed on with a cement gun, the latter method generally giving the best results. Some types of coating can be put on in much thicker layers, but care should be taken to assure that the coating selected will fit the particular brick used, otherwise it is apt to peel off in service. The coating seals the pores and openings in the brickwork and presents a more continuous and impervious service to the action of the furnace gases and slag; it is not a cure-all for refractory troubles.

Plastics and ramming mixtures are generally a mixture of fire clay and coarse grog of somewhat the same composition as the original fire-clay brick. They are used in repairing furnace walls which have been damaged by spalling or slag erosion, and also for making complete furnace walls in certain installations such as small boiler furnaces. They are also used to form special or irregular shapes, in temporary wooden forms, in the actual furnace construction.

Some of the plastics and ramming mixtures contain silicate of soda and are air setting, so that a strong structure is produced as soon as the material is dry. Others have as a base chrome ore or silicon carbide, which make a mixture having a high thermal conductivity and a good resistance to slag erosion. These mixtures are often used in the water walls of large boiler furnaces; they are rammed around the tubes and held in place by small studs welded to the tube walls. The chrome plastic has been used with good success for heating-furnace floors and subhearths of open-hearth furnaces.

Castable mixes are a refractory concrete usually containing high-alumina cement to give the setting properties. These find considerable use in forming intricate furnace parts in wooden molds; large structures have been satisfactorily cast by this method. This type of mixture is much used for baffles in boilers where it can be cast in place around the tubes. Lightweight castables with good insulating properties are used to line furnace doors.

Furnace Walls

The modern tendency in furnace construction is to make a comparatively thin wall, well supported by ironwork. The wall may be made of heavy refractories backed up with insulating material, or of insulating refractory. Table 7 gives heat losses and heat contents of a number of wall combinations and may enable the designer to pick out a wall section to suit his purpose.

Average values of VI for other crudes and their derivatives are about as follows: Mid-Continent, 70; East Texan, 60; Colombian, 40; Peruvian, 20.

By the use of addition compounds, such as paratone and acrylic ester, lubricating oils are raised to a higher viscosity index than normally obtained. Solvent refining also raises the viscosity index but has disadvantages that the oils are corrosive and are lower in lubricating value.

When lubricating oils are subjected to high pressure, there is a marked increase in viscosity. Paraffinic oils of high viscosity index vary less with pressure than do naphthenic oils, and fixed oils vary least.

Lubricants with good temperature-viscosity curves (high viscosity index) are desirable. In cold starting, the flatter the temperature-viscosity curve, the less the energy required and better the fluidity. In normal operation and at high temperatures and at high pressures, the flatter temperature-viscosity curve oils have less friction and higher load-carrying capacity.

Cloud and Pour Points. Petroleum oils, when cooled, may become plastic solids as a result either of partial separation of wax or of congealing of the hydrocarbons composing the oil. With some oils, the separation of wax becomes visible at temperatures slightly above the solidification point, and when that temperature is reached under prescribed conditions, it is known as the **cloud point** (A.S.T.M. D97-39). With oils in which wax does not separate prior to solidification, or in which the separation is invisible, the cloud point cannot be determined. That temperature at which the oil will just flow under prescribed conditions is known as the **pour point** (A.S.T.M. D97-39).

The pour point indicates the lowest temperature at which an oil will flow to the pump, bearings, or cylinder walls. It is particularly important for immediate oil circulation in connection with cold starting of engines, or with gravity lubricating systems, as the fluidity is a factor of pour point and viscosity of the cold oil. Pour-point depressants may be added to wax-containing oils to lower the pour points instead of dewaxing the oils.

Gravity. Lubricating-oil gravities are expressed either in specific gravity or A.P.I. gravity (see p. 85). Low-viscosity oils have higher A.P.I. gravities than the higher viscosity oils of the same crude-oil series. Paraffinic oils are the lightest or highest A.P.I. gravities, naphthenic are intermediate, and animal and vegetable oils are the heaviest or low A.P.I. gravity. The value of the sp gr s_1, at a temperature t_1 F, of a petroleum oil which has the sp gr s at 60 F is given approximately by the equation

$$s_1 = s - k(t_1 - 60)$$

where k has the following approximate values

$s =$	1	0.9	0.85	0.8	0.75	0.7
$k =$	0.00035	0.00035	0.00037	0.00040	0.00043	0.00048

The gravity of lubricating oils is of no value in predicting quality although it gives a clue to the source of the crude-oil base.

Flash and Fire Points. The flash point of an oil is the temperature to which an oil has to be heated until sufficient inflammable vapor is driven off to flash when brought into contact with a flame. The fire point is the higher temperature at which the oil vapors will continue to burn when ignited. The A.S.T.M. D92-33 standard method for flash and fire points by means of open cup tester is used for lubricating oils. In general, the open flash point is 30 F higher than the closed flash, and the fire point is some 50 to 70 F above this flash point.

unit. They have the advantage of low cost because of the light ironwork required to support them.

Many failures in furnace construction result from improper expansion joints. Expansion joints should usually be installed at least every 10 ft, although in some low-temperature structures the spacing may be greater. For high-temperature construction, the expansion joint allowance per foot in inches should be as follows: fire clay, $\frac{1}{16}$ to $\frac{3}{32}$; high alumina, $\frac{3}{32}$ to $\frac{1}{8}$; silica, $\frac{1}{8}$ to $\frac{3}{16}$; magnesite, $\frac{1}{4}$; chrome, $\frac{5}{32}$; forsterite, $\frac{1}{4}$. Figure 1 shows some typical examples of expansion joints. Corrugated cardboard is often used in the joints.

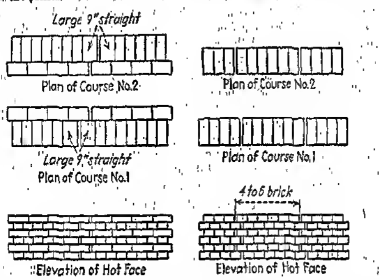

FIG. 1.—Expansion Joints.

The **roof** of the furnace is usually either a sprung arch or a suspended arch. A **sprung arch** is generally made of standard shapes using an inside radius equal to the total span. In most cases, it is necessary to build a form on which the arch is sprung. The arch dimensions can be calculated when the span and rise are known by the use of the table on p. 84. The number of brick per course is then easily determinable.

In the case of arches with a considerable rise, it has been found that an inverted catenary shape is better than a circular shape for stability, and it is possible to run the side walls of the furnace right down to the floor in one continuous arch with almost complete elimination of the ironwork. The catenary can be readily laid out by hanging a flexible chain from two points on a vertical wall.

The **suspended arch** is used when it is desirable to have a flat roof (curved suspended arches are also made); it presents certain advantages in construction and repair but is more difficult to insulate than the sprung arch. Special suspended arch shapes are commercially available. The insulating refractory is suited to this type of construction because the steel supports are light and the heat loss is low.

Selection of Refractories

The selection of the most suitable refractory for a given purpose demands experience in furnace construction. A brick that costs twice as much as another brand and gives twice the life is preferable since the total cost includes also the laying cost. Furthermore, a brick that gives longer service reduces

with 90 ml of petroleum naphtha as specified and centrifuged under prescribed conditions. The volume of sediment at the bottom of the centrifuge tube is reported as the A.S.T.M. precipitation number.

Corrosion and Neutralization Number. The usual method of checking lubricating oils for acidity is by determining the A.S.T.M. (D188-27T) neutralization number. The tests are designed to indicate, in petroleum lubricants and compounded products, the presence of organic constituents having acid characteristics and the contamination by alkalies and mineral acids. The neutralization number is the weight in milligrams of potassium hydroxide required to neutralize one gram of oil.

The neutralization number of used oil in no way indicates the corrosive action of the used oil in service. In some cases, a neutralization number of 1.0 may not attack the bearing metals; yet in other service tests of a different oil, 0.2 number will show high corrosive tendencies in short periods of operation.

Crude oils contain a natural inhibitor which is removed by the more drastic types of refining such as solvent extraction. Certain phosphite and sulphite additives have been used to check corrosion in lubricating oils. The use of oiliness additives in some instances may result in bearing corrosion especially where cadmium and certain lead-base bearings are used.

The Underwood bearing-corrosion test machine has been useful in the study of the corrosive resistance of lubricating oils. The bearing metals met with in service are used in the test so that their relationship to the oil in question is checked. In the Underwood tests, 0.01 percent of Fe_2O_3 is added, in the form of iron naphthenate, to accelerate the corrosion.

Products, such as slushing oils and greases, which are used to protect metal surfaces from corrosion are generally required to pass special tests. The tests measure the degree of protection afforded by the product under specified conditions such as salt spray or immersion in water.

Oiliness. The property of lubrication known as oiliness is of considerable importance. It is a phenomenon that becomes strongly evident only when the oil film separating rubbing surfaces is exceedingly thin. In films of molecular dimensions, viscosity effects are negligible although oiliness has a marked bearing. Oiliness depends on both the lubricant and the surface to which it is attached. Oiliness is the property that causes a difference in the friction when lubricants of the same viscosity at the same temperature and pressure of the film are used with different bearings.

Extreme-pressure Lubricants. The high tooth pressures and high rubbing velocities often encountered in hypoid and spur-type gearing have developed a class of lubricants called extreme-pressure or hypoid-gear lubricants. When mineral oils alone are used, metal to metal contact occurs which results in scoring, galling, and local seizure of the gear teeth. Most extreme-pressure lubricants are mineral oils containing loosely held sulphur or chlorine or some highly reactive material. The important characteristics of extreme-pressure lubricants are: ability to prevent galling or scoring; tendency to corrode; chemical stability; ability to reduce wear; ability to give low friction; and freedom from abrasive materials.

The S.A.E. film-strength testing machine is used for checking extreme-pressure and hypoid lubricants. This machine consists of a regular Timken bearing cup which rotates in contact with a second bearing cup at various speeds and rates of slippage. The hypoid-gear lubricants have higher load-carrying capacity at speeds above 750 rpm on the S.A.E. machine.

Properties of Various Lubricating Fats and Fatty Oils. Animal and vegetable fats and fatty oils are distinguished from mineral oils by being saponifiable with caustic alkalies. These organic oils oxidize, becoming rancid and setting free fatty acids. Oxidation also causes gumming particularly with cottonseed and corn oil. Subjected to high temperatures they tend to decompose to corrosive acids.

LUBRICANTS

BY

C. M. LARSON

Type and Properties. The correct type and properties of a lubricant are controlled by the application. The lubricant is manufactured to meet the service requirements of minimum coefficient of friction; maximum adhesion to the surfaces to be lubricated; maximum film strength; physical stability with regard to temperatures and pressure; chemical stability against oxidation; freedom from corrosive acids; resistance to emulsion; non-volatility; proper fluidity at low temperatures; minimum consistency; and purity control of abrasives, fillers, soaps, or addition agents.

Liquid-petroleum lubricants are generally used because of their suitability to modern engineering design. Greases, which are a mixture of mineral oil and soap, are recommended only where leakage is too high to retain liquid lubricants.

Petroleum Mineral Oils

The petroleum mineral oils are manufactured by fractionation of crude oils and are refined by acids or solvents and clay. Lubricating crude oils are mainly from the Pennsylvania, Mid-Continent, Gulf Coast, or California fields.

Physical tests of lubricants are widely used since their utility depends to a large extent upon their physical characteristics. The usual tests are viscosity, pour, gravity, flash and fire, demulsibility, and color; chemical tests comprise carbon residue, oxidation, corrosion, acidity, oiliness, extreme pressures, sulphur, and ash.

Viscosity. (See p. 244.) The Saybolt Universal viscometer (p. 244) is the standard instrument for testing petroleum products and lubricants; 100, 130, and 210 F are the temperatures specified (A.S.T.M. designation D88-38).

The variation of viscosity with temperature of petroleum oils may be determined with considerable accuracy when the viscosities are known at any two temperatures. The A.S.T.M. publishes charts for that purpose covering both Saybolt Universal viscosity and kinematic viscosity. If the two known points are plotted on the chart and are joined by a straight line, viscosities at other temperatures can be read off from that line. Figure 1 shows such a chart. The lines drawn on it are typical lines for the grades indicated.

S.A.E. Viscosity Number. The S.A.E. viscosity numbers for crankcase oils constitute a classification in terms of viscosity only. They are as follows:

Table 1. Properties of Animal and Vegetable Oils

Oil	Specific gravity at 60 F	Saponification number	Cold test, deg F	Flash test, deg F	Viscosity Saybolt, sec at 100 F	Price, cents per gal
Blown rapeseed	0.968	198–215	40	460	800–900	65
Castor oil	0.963	176–187	14	505	1485	85

25 deg paraffin	0.900	0.20	15	410	180	26

[a] At 210 F; is semisolid at 100 F.

soap stock. When the soap base has been prepared, mineral oil is added in small quantities and the mixing continued, heat having been supplied all the while by means of a steam coil. As the percentage of mineral oil is increased, the grease becomes softer. Soda greases are dehydrated (less than ½ percent moisture), whereas lime soap greases contain 1 to 2 percent moisture.

The A.S.T.M. **dropping point** of grease is the temperature at which it changes from a semisolid to a liquid state when the determination is made according to the prescribed A.S.T.M. D566-40T. Calcium- or lime-soap greases have melting points below 200 F; for dropping-points of 300 F or higher soda-soap greases are used.

The A.S.T.M. Method (D217-38T) is used in measuring the worked or the unworked **consistency** of lubricating greases which have a worked consistency less than 400. In this test, a standardized double-pitch cone is allowed to drop in the product at a definite temperature. The depth of penetration is measured. The unworked (original) consistency of lubricating greases is affected by the soap content, the kind of fat used, the method of manufacture, the final water content, the rate of cooling, and the basic metallic constituent of the soap. It is impractical to control the consistency of a grease to narrow limits. Any working or remelting of a grease after it is in the container will change the consistency. Although many tests are based on the unworked consistency, this property bears no definite relationship to worked values. Final tests are usually based on worked consistency (A.S.T.M.) where possible although hard railroad greases and soda-soap greases are tested for unworked consistency.

The texture of a grease refers to its structure such as smooth, fibrous, spongy, or rubbery. Calcium-base greases are smooth, soda-soap greases are fibrous or spongy, and aluminum-soap greases are stringy or rubbery.

The A.S.T.M. methods (D128-40) of **analysis** permit determination of the constituents of grease likely to be covered by specifications. Such constituents are soap base and content, fat, water, fillers, ash, excess alkali or acid, insaponifiable matter, and lubricating-oil content. Two greases showing the same analysis may show marked differences in lubricating performance and storage-stability properties. The soda-soap greases are more stable over much longer periods of service than lime-base greases.

Miscellaneous Oils and Lubricants

Air-compressor oils are refined straight mineral oils of S.A.E. 20 or 30 viscosity numbers. **Automobile and gasoline-engine oils** are well-

In the case of fluid grease, made by adding soap or other thickening ingredients to oil, the viscosity number by which the lubricant is classified is determined by the viscosity of the oil before the addition of the soap or other thickening ingredients. The S.A.E. viscosity numbers listed above are in general use for the description of lubricants for all uses.

The recommended minimum viscosities at operating temperatures for straight mineral oils are as follows:

	Viscosity, Saybolt sec
Well-designed high-speed bearings (turbines)	40
Automobile bearings (circulated oil)	45
Heavy-duty automotive engines (circulated oil)	70
Aircraft engines (circulated oil)	110
Reduction gears and speed reducers	200– 500
Transmissions and rear-axle gears	400– 1,000
Exposed gears	10,000–30,000

Viscosity index (VI) is an arbitrary method of stating the rate of change of viscosity of an oil with change of temperature. Pennsylvania crude oils, refined by conventional methods, suffer comparatively little change in viscosity with temperature; Gulf Coastal crudes change considerably. These two crudes and their fractions have been assigned viscosity index numbers of 100 and 0, respectively. The average viscosity characteristics of these two standardized oils have been obtained by Dean and Davis (*Chem. Met. Eng.*, 36, 1929, p. 618). The procedure in finding the VI of an oil is to determine its viscosity (Saybolt Universal) at 210 and at 100 F. The viscosities at 100 F of oils that have the same viscosity at 210 F, but are of VI 100 and 0, are then found from A.S.T.M. D567-40T. The VI of the oil under consideration is then found, by simple ratio, by comparison of its increase in viscosity from 210 to 100 F with the corresponding increases in the two standardized oils.

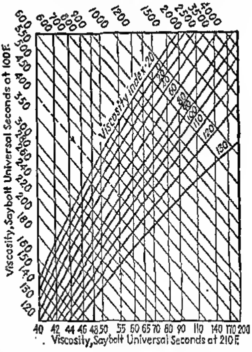

Fig. 2.—Viscosity-index Chart (Dean and Davis Scale).

Since the viscosity at 210 F is taken at the same value for all three oils, the VI of the oil under investigation can be written

$$\mathrm{VI} = \frac{L - U}{L - H} \times 100$$

where U, H, and L are the viscosities at 100 F of the oil under test, of the VI = 100 oil, and of the VI = 0 oil, respectively. Values of the VI may be obtained from Fig. 2. As shown by the broken lines the VI of an oil with SV of 55 at 210 F and 400 at 100 F is 80. It should be noted that values of VI may be negative or may exceed 100.

Flash and fire points depend upon the nature of the original crude oil, the viscosity, and the method of refining. For the same viscosities and degree of refinement, the paraffinic oils are higher than the naphthenic flash and fire points.

Steam Emulsion Test. A.S.T.M. D157-36 Steam Emulsion Test is used for lubricating oils and is commonly used for turbine oils. This method is suitable for use on all oils when emulsion, demulsibility, or emulsification tests are required. The Steam Emulsion number (S.E. No.) is the number of seconds required for an oil to separate when emulsified and separated under prescribed conditions.

The demulsification of pure well-refined mineral oils is very good below 300 S.E. No. Next to viscosity, the demulsibility is the most important test for steam-turbine oils. There is some doubt as to the necessity of high demulsification of lubricants for other service applications.

Color. The color of a lubricating oil is obtained by reference to transmitted light. The color by reflected light, called the bloom, is a distinctive feature capable of giving information on the origin and refining of the oil.

The color of an oil may vary with regard to intensity of light transmitted. Color measurement (A.S.T.M. D155-39T) is intended for the determination of lubricating oils through the use of the A.S.T.M. Union Colorimeter. The A.S.T.M. color numbers range from 1 (lily white) to 8 (darker than claret red). Oils darker than 8 color are diluted with kerosine (15 percent lubricating oil and 85 percent by volume of kerosine) and are then observed in the same way as lighter colored oils.

Carbon Residue. The Conradson carbon-residue test (A.S.T.M. D189-39) is a means of determining the amount of carbon residue left on evaporating an oil under specified conditions and is intended to throw some light on the relative carbon-forming properties of an oil. The carbon-residue test was originally developed for comparison of the carbon-forming properties of lubricating oils for internal-combustion engines. The deposits vary with the type and mechanical condition of the engine, the service conditions, the time of continuous operation, the viscosity of the oil, and the carburation of the fuel. Modern refining methods tend to make this test less useful for predicting carbon-forming tendency of motor oils.

The Ramsbottom coking test (A.S.T.M. D524-40T) is widely used in Great Britain and yields more reproducible results than the Conradson test. The A.S.T.M. has recommended that the Conradson test be replaced by the Ramsbottom test. The carbon residues from the two methods are not comparable.

Ash. The ash determination of lubricating oil is conducted on the carbon remaining after the carbon-residue test. The nature of the ash is used to determine iron (rate of wear), sand or grit (from atmosphere), or lead (from leaded gasoline) in the used lubricating oil.

Oxidation Testing Methods. Lubricating oils may be subjected to relatively high temperatures in the presence of air and catalytically active metals or metallic compounds. The resultant oxidation of the oil develops increased viscosity, acids, carbon residue, sludge, and asphaltenes. There are several oxidation tests. The Navy Work Factor (*U. S. Navy, Bur. Ships*, N.B.S. 431—1940) and the U. S. Army Oxidation Test (No. 29 LA, Mar. 1, 1938, F5) are met in aircraft lubricating-oil specifications.

When the carbon residue of motor oils is lowered below certain limits, the oxidation products are soluble in hot oil and lacquer deposits form on the metallic surfaces such as on the pistons, in the ring grooves, and on the inlet valve stems where there are low rates of oil flow in internal-combustion engines. It appears that the unsaturated and asphaltic constituents yield a sludge of carbonaceous matter and the pure paraffins of high solvent refining form corrosive acids.

Phosphites are being tried as antioxidant addition agents in gasoline-engine lubricating oils. The tin salts also have been tried. In the Diesel engine field, calcium-base addition agents have been used successfully to prevent sludge and ring sticking.

Precipitation Number. Steam cylinder oils and black oils are checked by the (A.S.T.M. D91-40) precipitation number. This method is also applied to used crankcase oils of internal-combustion engines to check the oxidized products, carbonaceous matter, and asphaltenes formed through use. The A.S.T.M. precipitation number is the number of milliliters of precipitate formed when 10 ml of lubricating oil are mixed

MECHANISM

BY

B. E. THOROGOOD

REFERENCES: Reuleaux, "Kinematics of Machinery," Macmillan. Unwin, "Elements of Machine Design," Longmans. Schwamb and Merrill, "Elements of Mechanism," Wiley.

Definition. A mechanism is that part of a machine which contains two or more pieces so arranged that the motion of one compels the motion of the others according to a definite law depending upon the nature of the combination.

Linkages

Links may be of any form so long as they do not interfere with the desired motion. The simplest form is that of four bars, *A*, *B*, *C*, *D*, fastened together at their ends by cylindrical pins, and which are all movable in parallel planes. If the links are of different lengths and each is fixed in turn, there will be four possible combinations; but as two of these are similar there will be produced three mechanisms having distinctly different motions. Thus, in Fig. 1, if

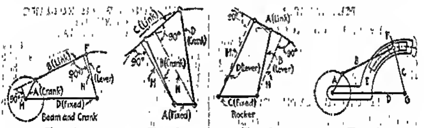

FIG. 1. FIG. 2. FIG. 3. FIG. 4.

D is fixed *A* can rotate and *C* oscillate, giving the **beam-and-crank** mechanism, as used on side-wheel steamers. If *B* is fixed the same motion will result; but if *A* is fixed (Fig. 2) links *B* and *D* can rotate, giving the **drag-link** mechanism used to feather the floats on paddle wheels. Fixing link *C* (Fig. 3), *D* and *B* can only oscillate, and a **rocker** mechanism sometimes used in straight-line motions is produced. It is customary to call a rotating link a **crank**; an oscillating link a **lever**, or beam; and the connecting link a **connecting rod**. The fixed link is often enlarged and used as the supporting frame.

If in the linkage (Fig. 1) the pin joint *F* is replaced by a slotted piece *E* (Fig. 4) no change will be produced in the resulting motion, and if the length of links *C* and *D* is made infinite the slotted piece *E* will become straight and the motion of the slide will be that of pure translation, thus obtaining the engine, or **sliding-block, linkage** (Fig. 5).

If in the sliding-block linkage (Fig. 5) the long link *B* is fixed (Fig. 6), *A* will rotate and *E* will oscillate and the infinite links *C* and *D* may be indicated as shown. This gives the **swinging-block linkage**. When used as a quick-return motion the slotted piece and slide are usually interchanged (Fig. 7) which in no way changes the resulting motion. If the short link *A* is fixed (Fig. 8) *B* and *E* can both rotate, and the mechanism known as the **turning-block linkage** is obtained. This is better known under the name of the

Saponification Number. The saponification number (A.S.T.M. D94-39T) of animal and vegetable oils and of compounded lubricants is the number of milligrams of potassium hydroxide required to saponify 1 g of oil. It is a measure of both free and combined fatty acids. When the sample contains appreciable amounts of sulphur and sulphurized oils, the saponification number obtained will be greater for the amount of fatty matter actually present. The percentage of fatty oil (or fat) in a compounded petroleum product can be calculated from the saponification number when the fatty oil is known (see Table 1). Unless the saponification number is known, commercial practice uses a value 195 for calculation.

The saponification number is the best obtainable index of the percentage of fat or fatty oil in a given lubricant.

Animal Oils. Animal oils are commonly obtained by rendering the fatty parts of the different animals, usually with high-pressure steam. Extraction with solvents is seldom practiced. As a result of the rendering operation, a more or less solid fat is obtained, as beef tallow, mutton tallow, or lard. When this is chilled and pressed, the corresponding oil and stearin result. **Tallow** should be "acidless," *i.e.*, free from sulphuric acid and contain only the smallest possible quantity of free fatty acid. It is hard and does not turn rancid easily. It forms a constituent of belt dressings, cylinder oils, and lubricating greases. **Tallow oil** is obtained by chilling and pressing tallow; it is a light-yellow bland oil used for mixing with steam cylinder oils. **Lard oil** is prepared similarly to tallow oil and appears in the market in five or six different varieties including Prime, Pure, No. 1, and No. 2, which are graded according to color, the first being very light straw-yellow and the last dark brown and ill-smelling: it is used in thread-cutting oils. **Neatsfoot oil** is obtained by boiling the bones of the feet of horned cattle with water and running off the oil. It is often adulterated with sheep and horse-foot and hide oil, as well as rape, cottonseed, and mineral oils. It is light yellow and bland, with little tendency to turn rancid. It is used similarly to lard oil and particularly for softening leather. **Whale oil** is made by rendering the blubber of various species of whales, and consequently is of very variable composition. It is used as a leather dressing and to mix with other oils as a lubricant. **Sperm oil** comes from the great cavity in the head of the sperm whale and also from its blubber. It is a limpid, pale yellow oil adapted for fine machinery. **Degras** is the grease obtained in scouring wool. It usually contains sulphuric acid, except when made by the naphtha-extraction process. It possesses the property of emulsifying with water to a marked degree and finds use as a leather dressing and in cylinder oils.

Vegetable Oils. Vegetable oils are usually prepared by pressing the crushed cooked seed or by extraction with benzine or carbon bisulphide. The chief vegetable oils are castor, corn, cottonseed, and rape. **Castor oil,** obtained from the castor bean, is a very viscous oil which gums on standing and does not naturally mix well with mineral oils. To render this possible, it is heated to 212 F and a current of air forced through, whereby it becomes more viscous and is known as "blown oil." **Cottonseed oil** is a pale or deep yellow oil of slight drying properties, chiefly used as an adulterant for other oils and, as well as rapeseed and castor, for the manufacture of blown oils. **Corn** (or maize) **oil** is a somewhat viscous oil with some drying properties. It is used with cottonseed oil for the preparation of soft soaps for lubricating greases. **Rapeseed oil** should be clear, *i.e.*, free from gelatinous matter. Blown rapeseed is compounded with mineral oils for marine steam-engine oils.

Greases. Grease is a mineral oil that has been thickened by compounding with soap. An alkali, usually lime or soda, is mixed with a fat to form the

representing the velocities of any number of points on the link will be on a straight line (Fig. 12): abc = a straight line. To find the velocity of any point when the velocity and direction of any two other points are known, condition (2) may be used, or a combination of (1) and (3). The **linear velocity ratio** of any two points on a linkage may be found by determining the distances e and f to the instant center (Fig. 13); then $V_c/V_b = e/f$. This may often be simplified by noting that a line drawn parallel to e and cutting B produced, forms two similar triangles efB and sAy, which gives $V_c/V_b = e/f = s/A$.

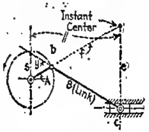

FIG. 13.

The angular velocity ratio for any position of two oscillating or rotating links A and C (Fig. 1), connected by a movable link B, may be determined by scaling the length of the perpendiculars M and N from the axes of rotation to the center line of the movable link. The angular velocity ratio is inversely proportional to these perpendiculars, or $O_C/O_A = M/N$. This method may be applied directly to a linkage having a sliding pair if the two infinite links are redrawn perpendicular to the sliding pair, as indicated in Fig. 14. M and N are also shown in Figs. 1, 2, 3, 5, 6, 8. In Fig. 5 one of the axes is at infinity, therefore N is infinite, or the slide has pure translation.

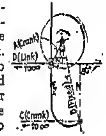

FIG. 14.

Forces. A mechanism must deliver as much work as it receives, neglecting friction, therefore the force at any point F multiplied by the velocity V_F in the direction of the force at that point must equal the force at some other point P multiplied by the velocity V_P at that point; or the forces are inversely as their velocities and $F/P = V_P/V_F$. It is at times more convenient to equate the moments of the forces acting around each axis of rotation (sometimes using the instant center) to determine the force acting at some other point. Applying this to Fig. 15, $(F \times a \times c)/(b \times d) = P$.

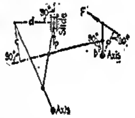

FIG. 15.

CAMS

Cam Diagrams. A cam is usually a plate or cylinder which communicates motion to a follower by means of its edge or a groove cut in its surface. In the practical design of cams the angular velocity ratio is not directly involved, but the follower must assume a definite series of positions while the driver occupies a corresponding series of positions. The relationship of driver to follower may be represented by a diagram in which the ordinates represent the rise or fall of the follower and the abscissas the angular motion of the cam.

FIG. 16.

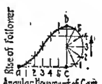

FIG. 17.

The three most common forms of motion used are uniform motion (Fig. 16), harmonic motion (Fig. 17), and uniformly accelerated and retarded motion

refined straight mineral *oils with low carbon residue, low pour points*, and free from corrosive acids. **Belt dressings** are (1) mixtures of solid fats, waxes, degras, or tallow with castor or fatty oils; (2) vulcanized corn or cottonseed oil thinned with naphtha; (3) preparations containing rosin which is undesirable (see also p. 700): (4) neats foot oil. **Black oils** (summer and winter) or **well oils** are reduced *crude oil from which the* naphtha, illuminating, and gas oils have been removed by distillation. The summer oils have higher viscosity and the winter oils zero pour points. **Car or journal-box oils** (summer and winter) are usually made from a light subzero pour oil blended to suitable viscosities with heavy cylinder or residuum oils to meet climatic conditions. *The minimum of winter grade is* 40 sec Saybolt at 210 F. The summer grade is about 60 sec at 210 F. Car or journal-box oils are more highly refined than black or well oils. **Chassis grease or pressure-gun grease** are lime or lime soda greases, using at least an S.A.E. 30 grade oil; *they have the proper consistency* to feed through pressure guns and yet do *not drip from the shackles or bearings*. **Crankcase oils** *are filtered straight* mineral oils and are usually light turbine oils which do not emulsify with water. **Cylinder or valve oils** are mixtures of S.A.E. 60 or 70 mineral oils and 3 to 10 percent animal oils, the percentage of compound decreasing with increasing dryness of steam. When straight mineral, they are prefixed *mineral*. **Superheat valve oils** *have high flash and fire and are 180 sec* or higher Saybolt viscosity at 210 F. **Cutting oils** are S.A.E. 10 or 20 petroleum oils, usually engine oils, compounded with 10 to 30 percent lard oil or S.A.E. 10 or 50 oils blended with sulphurized-lard or sulphur-chloride-lard base. **Diesel-engine oils** are highly filtered straight mineral oils, usually *of S.A.E. 10, 20, 30, or 40 viscosity numbers. The four-cycle engines work* well on Gulf Coast oils whereas for the two-cycle, Pennsylvania oils are recommended. **Dynamo or electric-motor oils** are well-refined straight mineral oils, S.A.E. 10 or 20 grades. Where low temperatures are encountered, zero pour or lower is required. **Engine and machine oils** are straight *mineral oils of S.A.E. 10 or 20 grades, either red or pale color.* The degree of refinement depends on whether moisture comes in contact and if oil is reclaimed. **Graphite or plumbago** (see p. 714) should be finely ground and low in ash or abrasives. When mixed with grease in proportions of 2 to 18 percent, the result is graphite grease. **Oildag, aquadag, and gredag** are *colloidal suspensions of artificial* deflocculated *graphite in oil,* water and grease, respectively (see p. 715). **Marine-engine oils** are petroleum oils of S.A.E. 20 or 40 grades, compounded with lard oil or blown rapeseed. They should emulsify with water. **Non-fluid oils** are light pale petroleum oils with small percentages of lime soap or aluminum oleate. **Pinion or gear greases** *are either straight petroleum products of 500 to 5,000 sec* Saybolt viscosity at 210 F or heavy mineral cylinder oils with rosin, talc, graphite, or asbestos. **Soluble oils** are pale mineral oils, light S.A.E. 10 grade with soap or water-saponifiable oil. When added to water, they saponify immediately into a milky oily cutting or grinding solution. **Spindle oils** (textile) are highly *refined pale or lily-white oils of light S.A.E. 10 body.* For a stainless spindle oil, the lily-white-color oil is compounded with prime lard oil. **Transformer oils** are highly refined filtered light-petroleum oils, water free, so as to have high dielectric strength. **Turbine oils** are highly refined filtered pale oils with high demulsibility. They are S.A.E. 10 grade except for geared turbines *where S.A.E. 20 or 30 body is* used or S.A.E. 30 or 70 viscosity number for ring-oiled turbine grades. **Watch oil** is obtained from the porpoise, dolphin, or blackfish where it exists in the cavities in the jaw and in the brain or "melon" of the fish.

CYLINDRICAL CAM (Fig. 22). **In this type of cam more than one complet turn may be obtained, provided that in all cases the follower returns to it starting point.** Draw rectangle *wxyz* (Fig. 22) representing the developmen of cylindrical surface of the cam. Subdivide the desired motion of the fol lower *bc* horizontally in the manner indicated in Figs. 16, 17, and 18, and plo the corresponding angular displacements 1′, 2′, 3′, etc., of the cam vertically then through the intersection of lines from these points draw a smooth curve This may best be shown by an example, assuming the following data for th diagram in Fig. 22: Total motion of follower = *bc*; circumference of cam = $2\pi r$. Follower to move with harmonic motion 4 units to the right in 0.6 turn then rest (or "dwell") 0.4 turn, and finish with uniform motion 6 units to th right and 10 units to the left in two turns.

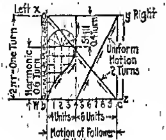

FIG. 22.

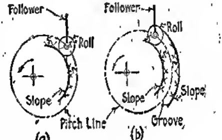

FIG. 23.

Cam Design. In the practical design of cams the following point must be noted. If only a small force is to be transmitted, sliding con tact may be used, otherwise **rolling contact.** For the latter the pitch lin must be corrected in order to get the true slope of the cam. An approximat construction (Fig. 23) may be employed by using the pitch line as the cente of a series of arcs the radii of which are equal to that of the follower roll to b used; then a smooth curve drawn tangent to the arcs will give the slop desired for a roll working on the periphery of the cam (Fig. 23*a*) or in a groov (Fig. 23*b*). For plate cams the roll should be a small cylinder, as in Fig 24*a*. In cylindrical cams it is usually sufficiently accurate to make th

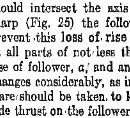

FIG. 24.

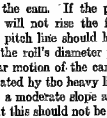

FIG. 25.

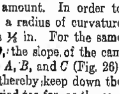

FIG. 26.

roll conical, as in Fig. 24*b*, in which case the taper of the roll produce should intersect the axis of the cam. If the pitch line *abc* is made to sharp (Fig. 25) the follower will not rise the full amount. In order t prevent this loss of rise the pitch line should have a radius of curvatur at all parts of not less than the roll's diameter plus ⅛ in. For the sam rise of follower, *a*, and angular motion of the cam, *O*, the slope of the cam changes considerably, as indicated by the heavy lines *A*, *B*, and *C* (Fig. 26) Care should be taken to keep a moderate slope and thereby keep down th side thrust on the follower, but this should not be carried too far, as the cam would become too large and the friction increase.

and D will have rotated the amount indicated in the tabulation. Then the algebraic sum will give the relative turns of each gear. That is, in Fig. 31, for one turn of the arm, *B does not move and C turns in the same direction $3\frac{1}{2}$ rev, and D in the opposite* direction $\frac{1}{4}$ rev; whereas in Fig. 32, for one turn of the arm, B does not turn, but C and D turn in the same direction as the arm respectively $2\frac{1}{2}$ and $1\frac{3}{7}$ rev. (Note: The arm in the above case was turned $+1$ for convenience, but any other value might be used.)

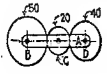

Fig. 31.

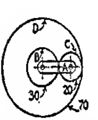

Fig. 32.

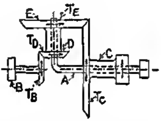

Fig. 34.

Fig. 35.

Bevel epicyclic trains are epicyclic trains containing bevel gears and may be calculated by the preceding method, but it is usually simpler to use the general formula which applies to all cases of epicyclic trains:

$$\frac{\text{Turns of } C \text{ relative to arm}}{\text{Turns of } B \text{ relative to arm}} = \frac{\text{Absolute turns of } C - \text{turns of arm}}{\text{Absolute turns of } B - \text{turns of arm}}$$

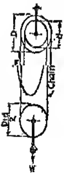

Fig. 36.

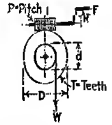

Fig. 37.

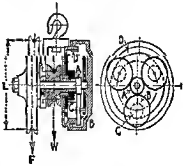

Fig. 38.

The left-hand term gives the value of the train and can always be expressed in terms of the number of teeth (T) on the gears; care must be used, however, to express it as either plus (+) or minus (−), depending upon whether the gears turn in the same or opposite directions.

$$\frac{\text{Relative turns of } C}{\text{Relative turns of } B} = \frac{C - A}{B - A} = -1, \text{ in Fig. 33; } = +\frac{T_B}{T_C} \times \frac{T_E}{T_D} \text{ in Fig. 34.}$$

Whitworth quick-return motion, and is generally constructed as in Fig. 9. The **ratio of time of advance to time of return** H/K of the two quick-return motions (Figs. 7 and 9) may be found by locating, in the case of the swinging block (Fig. 7), the two tangent points (t) and measuring the angles H and K made by the two positions of the crank A. If H and K are

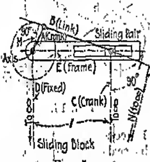

FIG. 5.

FIG. 6.

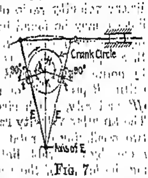

FIG. 7.

known the axis of E may be located by laying off the angles H and K on the crank circle and drawing the tangents E, their intersection giving the desired point. For the turning-block linkage (Fig. 9), determine the angles H and K made by the crank B when E is in the horizontal position; or, if the angles are known, the axis of E may be determined by drawing a

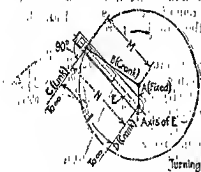

FIG. 8.

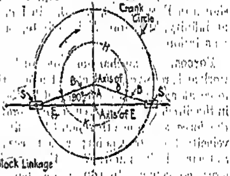

FIG. 9.

horizontal line through the two crank-pin positions (S) for the given angle, and the point where a line through the axis of B cuts E perpendicularly will be the axis of E.

Velocities of any two or more points on a link must fulfill the following conditions (see p. 195): (1) Components along the link must be equal and

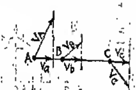

FIG. 10.

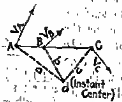

FIG. 11.

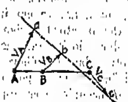

FIG. 12.

in the same direction (Fig. 10): $V_a = V_b = V_c$. (2) Perpendiculars to V_A, V_B, V_C from the points A, B, C must intersect at a common point d, the **instant center** (or **instantaneous axis**). (3) The velocities of points A, B and C are directly proportional to their distances from this center (Fig. 11): $V_A/a = V_B/b = V_C/c$. For a straight link the tips of the vectors

SCREW FASTENINGS

Machine Screw Threads: Forms and Proportions

The American (National) Standard thread (formerly called the Sellers or U. S. Standard thread) for machine screws, shown in Fig. 1, is proportioned by the formulas p = pitch = 1/No. of threads per inch, d = depth = $0.6495p$, f = flat = $p/8$. See Table 1.

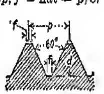

FIG. 1.—American (National).

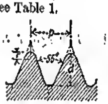

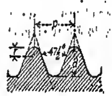

FIG. 2.—Whitworth. FIG. 3.—British Association. Standard Screw Threads.

The Whitworth Standard thread (Fig. 2) is used in Great Britain and is based on the formulas $d = 0.6403p$, r = radius = $0.1373p$. See Table 2.

The British Association screw thread is shown in Fig. 3, and dimensions of bolts with such threads are given in Table 3.

The French (Metric) screw thread (Fig. 4) is based on the formulae p = pitch in mm., $d = 0.6495p$, $f = p/8$. See Table 4.

(Fig. 18). In plotting the diagrams (Fig. 18) for this last motion, divide ac into an even number of equal parts and bc into the same number of parts with lengths increasing by a constant increment to a maximum and then decreasing by the same decrement, as, for example, 1, 3, 5, 5, 3, 1, or 1, 3, 5, 7, 9, 9, 7, 5, 3, 1. In order to prevent shock when the direction of motion changes, as at a and b in the uniform motion, the harmonic motion may be used; if the cam is to be operated at high speed, the uniformly accelerated and retarded motion should preferably be employed; in either case there is a very gradual change of velocity.

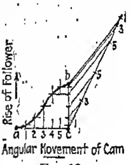

FIG. 18.

Pitch Line. The actual pitch line of a cam varies with the type of motion and with the position of the follower relative to the cam's axis. Most cams as ordinarily constructed are covered by the following four cases.

FOLLOWER ON LINE OF AXIS (Fig. 19). To draw the pitch line, subdivide the motion bc of the follower in the manner indicated in Figs. 10, 17, 18. Draw a circle with a radius equal to the smallest radius of the cam $a0$ and subdivide it into angles $0a1'$; $0a2'$, $0a3'$, etc., corresponding with angular displacements of the cam for positions 1, 2, 3, etc., of the follower. With a as a center and radii $a1$, $a2$, $a3$, etc., strike arcs cutting radial lines at d, e, f, etc. Draw smooth curve through points d, e, f, etc.

OFFSET FOLLOWER (Fig. 20). Divide bc as indicated in Figs. 16, 17, and 18. Draw a circle of radius ac (highest point of rise of follower) and one tangent to cb produced. Divide the outer circle into parts 1′, 2′, 3′, etc., corresponding with the angular displacement of the cam for positions 1, 2, 3, etc., of the follower, and draw tangents from points 1′, 2′, 3′, etc., to the small circle. With a as a center and radii $a1$, $a2$, $a3$, etc., strike arcs cutting tangents at d, e, f, etc. Draw a smooth curve through d, e, f, etc.

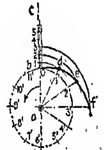

FIG. 19.

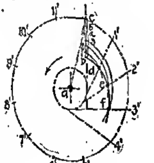

FIG. 20.

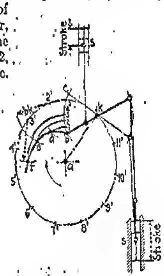

FIG. 21.

ROCKER FOLLOWER (Fig. 21). Divide the stroke of the slide S in the manner indicated in Figs. 16, 17, and 18, and transfer these points to the arc bc as points 1, 2, 3, etc. Draw a circle of radius ak and divide it into parts 1′, 2′, 3′, etc., corresponding with angular displacements of the cam for positions 1, 2, 3, etc., of the follower. With k, 1′, 2′, 3′ etc., as centers and radius bk, strike arcs kb, $1'd$, $2'e$, $3'f$, etc., cutting at $bdef$ arcs struck with a as a center and radii ab, $a1$, $a2$, $a3$, etc. Draw a smooth curve through b, d, e, f, etc.

Standard Screw Threads for Bolts, Machine Screws, Nuts, and Commercially Tapped Holes

The National Screw Thread Commission appointed by Congress in 1918 to standardize and unify screw threads presented a revised report in 1928 and a further revision in 1933. This was issued as *N. B.S. Misc. Pub.* 141 and reference to it for all matters relating to screw threads for various uses should be made.

The report includes certain additions to the coarse-thread series and to the fine-thread series but eliminates all sizes above 1¾ in. in the latter series. It also makes certain additions to hose-coupling threads and revises the tolerances for pipe-thread gages. Specification for Acme threads are also revised.

The thread profile is that previously known as the Sellers or U. S. Standard (see p. 758) and is to be known hereafter as the **American (National) form of thread.** Two thread series are adopted, a coarse-thread and a fine-thread series with basic diameters and threads per inch substantially as given in Table 10, p. 764. The coarse-thread series is recommended for general engineering work and where rapid and easy assembly is desired; the fine-thread series is recommended for automotive and airplane use and wherever minimum weight is a desideratum. Four classes of fits are specified: (1) **Loose fits** are recommended as a commercial standard for tapped holes in the numbered (small) sizes only and for rough work when ease of assembly is desirable and snugness of fit is unnecessary. (2) **Free fits** include the great bulk of screw-thread work of ordinary quality of finished and semifinished bolts and nuts, etc. (3) **Medium fits** include the better grades of interchangeable screw-thread work such as automobile bolts and nuts. (4) **Close fits** include work requiring a fine snug fit such as is necessary in airplane work. In this class of fits, selective assembly of parts may be necessary. This is not practicable as a commercial standard for tapped holes of the numbered (small) sizes. The same quality of fit as given by medium-fit screws and threaded holes can be obtained by using screws to free-fit tolerances in holes made to close-fit tolerances, or vice versa.

The following specifications apply to all classes of fit, except loose-fit.

Uniform Minimum Nut. The pitch diameter of the minimum threaded hole or nut corresponds to the basic size, variations being permitted above the basic size. The major and minor diameters of the minimum nut are the same for all classes.

Uniform Tap Drill Sizes. The maximum and minimum minor diameters are the same for all nuts of a given size for all classes of fit. This permits uniform tap-drill sizes for all classes of fit.

Uniform Major and Minor Diameter of Screws. The maximum and minimum major and minor diameters are the same for all screws of a given size for all classes of fit.

Length of Engagement. The tolerances are based on a length of engagement not to exceed the nominal diameter of the thread. Where greater lengths of engagement are required, a corresponding increase in accuracy is necessary.

Limiting dimensions and tolerances for free, medium, and close fits are given in Table 5, which also includes tolerances for nuts of loose fit in the numbered sizes only. If larger tolerances are required than those given for free fit, the loose-fit dimensions of Table 6 may be used. With loose fit, the minimum nut diameter is basic as with the other fits but the maximum screw diameter is below basic.

Additional dimensions to those given in Table 5 are as follows:

Screws. Maximum major diameter = basic major diameter (Col. 3). Minimum major diameter = Col. 3—Col 5. Maximum pitch diameter = basic pitch diameter (Col. 4). Minimum pitch diameter = Col. 4—Col. 9, 10, 11, or 12.

Nuts. Minimum major diameter = basic major diameter (Col. 3). Minimum pitch diameter = basic pitch diameter (Col. 4). Maximum pitch diameter = Col. 4 + Col. 9, 10, 11, or 12. Minimum minor diameter = Col. 7—Col. 8.

Rolling Surfaces

In order to connect two shafts so that they shall have a definite angular velocity ratio, rolling surfaces are often used; and in order to have no slipping between the surfaces they must fulfill the following two conditions; the line of centers must pass through the point of contact, and the arcs of contact must be of equal length. The angular velocities, expressed usually in rpm, will be inversely proportional to the radii: $N/n = r/R$. The two surfaces most commonly used in practice, and the only ones having a constant angular velocity ratio, are cylinders where the shafts are parallel, and cones where the shafts (produced) intersect at an angle. In either case there are two possible directions of rotation, depending upon whether the surfaces roll in opposite directions (external contact) or in the same direction (internal contact). In Fig. 27, $R = nc/(N + n)$ and $r = Nc/(N + n)$; in Fig. 28, $R = nc/(N - n)$ and $r = Nc/(N - n)$. In Fig. 29, $\tan B = \sin A/[(n/N) + \cos A]$, and $\tan C = \sin A/[(N/n) + \cos A]$; in Fig. 30, $\tan B = \sin A/[(n/N) - \cos A]$, and $\tan C = \sin A/[(N/n) - \cos A]$. With the above values for the angles B and C, and the length d or e of one of the cones, R and r may be calculated.

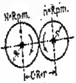

FIG. 27.

FIG. 28.

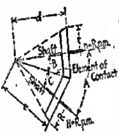

FIG. 29.

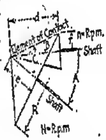

FIG. 30.

Epicyclic Trains

Epicyclic trains are combinations of gears in which some or all of the gears have a motion compounded of rotation about an axis and a translation or revolution of that axis. The gears are usually connected by a link called an arm, which often rotates about the axis of the first gear. Such trains may be calculated by first considering all gears locked and the arm turned; then the arm locked and the gears rotated. The algebraic sum of the separate motions will give the desired result. The following examples and method of tabulation will illustrate this. The figures on each gear refer to the number of teeth for that gear.

	A	B	C	D
Gear locked, Fig. 31	+1	+1	+1	+1
Arm locked, Fig. 31	0	−1	$+1 \times {}^{50}/_{20}$	$-1 \times {}^{50}/_{20} \times {}^{20}/_{40}$
Addition, Fig. 31	+1	0	$+3\frac{1}{2}$	$-\frac{1}{4}$
Gears locked, Fig. 32	+1	+1	+1	+1
Arm locked, Fig. 32	0	−1	$+1 \times {}^{30}/_{20}$	$+1 \times {}^{30}/_{20} \times {}^{20}/_{40}$
Addition, Fig. 32	+1	0	$+2\frac{1}{2}$	$+1\frac{3}{4}$

For common epicyclic trains, see also p. 817.

In Figs. 31 and 32 lock the gears and turn the arm A right-handed through 1 revolution (+1), then lock the arm and turn the gear B back to where it started (−1); gears C

Hoisting Mechanisms

Pulley Block (Fig. 35). Given the weight W to be raised, the force F necessary is $F = V_W \times W/V_F = W/n$ = load/number of ropes; V_W and V_F being the respective velocities of W and F.

Differential Chain Block (Fig. 36). $F = V_W \times W/V_F = W(D - d)/2D$.

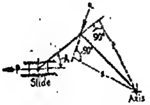

FIG. 39.

Worm and Wheel (Fig. 37). $F = \pi d(n/T)W/2\pi R = WP(d/D)/2\pi R$, where n = number of threads, single, double, triple, etc.

The triplex chain block (Fig. 38) is a geared hoist making use of the epicyclic train. $F = W \times M/L\{1 + [(T_D/T_C) \times (T_B/T_A)]\}$, where T = number of teeth on gears.

Toggle Joint (Fig. 39). $P = F \times s \cos A/t$.

The Buttress thread (Fig. 8) is a strong form, adapted for taking load in one direction only.

The Dardelet thread (Fig. 9) made by the Dardelet Threadlock Corp., New York, is a thread on which the nut is self-locking. It is similar to the Acme thread; the sides are inclined at 14 1/2 deg.

Fig. 9.—Dardelet Thread.

The S.A.E. Standard Screw-thread Series (Aug., 1922) includes a coarse-thread series sometimes called the **American** or **National Coarse Screw-thread Series,** which in the numbered sizes below 1/4 in. correspond to the Special Standard of the A.S.M.E. (1907) and from 1/4 in. up are the same as the

The Whitworth pipe thread is the standard used in Great Britain. It is cut either straight or with a taper of ¾ in. per ft as in the Briggs standard.

Table 12. Whitworth Pipe Threads

Number of threads per inch: ⅛ in., 28; ¼ and ⅜ in., 19; ½, ⅝, ¾ and ⅞ in., 14; 1 in. and larger, 11.

Bolt Machine Screw Heads and Nuts: Forms and Proportions

The **A.S.M.E. Standard machine screws** have threads of the same form and proportions as the American (National) Standard (Fig. 1). The following diameters and pitches are standardized, the relation being: threads per in. $= 6.5/(\text{diameter} + 0.02)$. Certain special pitches are also recommended in addition to the standards.

Table 13. A.S.M.E. Standard Machine Screws (1907)

30	0.4526	14, 16	*U*	0.368	3/4 – 4

Standard lengths vary by the following increments: 1/8 in. to 1 in. by 1/16 in.; 1 in. to 2 in. by 1/8 in.; 2 in. to 4 in. by 1/4 in.

Thread-cutting screws, made by the Shakeproof Lock Washer Co., Chicago, are adaptable to the American National Coarse- and Fine-thread Series and have been standardized from No. 4 screw to 3/8 in. diameter and for metal thicknesses up to 1/2 in. These are supplied in all types of head.

Eyebolts used by the Union Iron Works are made to the proportions given in Fig. 15 and Table 22.

Table 22. Proportions of Eyebolts
(See Fig. 15)

Diam of bolt, in.	Diam of stock in eye, in.	A, in.	B, in.	C, in.	D, in.	E, in.	F, in.	Capacity, lb

1 7/8	1 1/4	4	6 1/2	4	3	3 1/2	7	19,150
2	1 1/4	4	6 1/2	4	3	3 1/2	7	22,340

Strength of Eyebolts. The following formula by C. M. Sames (*Ind. Eng.*, Sept., 1911) closely represents the practice of the General Electric Co.: Load in lb at which deformation begins $= 33{,}000\ d^3/(D_1 - 1.2D_2)$, in which d = diam of stock in eye, D_1 = mean diam of eye (= internal diam + d), and D_2 = diam of bolt shank at root of thread—all in inches. In designing, for eyebolts forged from double refined iron, take safe load equal to 1/2 that given by formula.

American Standard, Table 1; a fine-thread series, sometimes called the **American** or **National Fine Series,** which in the numbered sizes corresponds to the A.S.M.E. Standard (1907) and from ¼ in. up with the S.A.E. Standard, Table 23; and an **extra-fine series** (S.A.E., 1915).

Screw Threads for Pipes

The American National taper pipe thread was formerly known as the Briggs pipe thread. Its form is shown in Fig. 10, and it is made to the following specifications: Taper of pipe end = ¾ in. per ft = 1 in 16. Depth of thread, $h = 0.8 \times$ pitch (p). Pitch diameter at end of pipe, $E_0 = D - (0.05D + 1.1)p$. Length of effective thread, $L_2 = p(0.8D + 6.8)$. D = outside diameter of pipe (see p. 907). See Table 11. Further details in A.S.A., B2.

For O.D. pipe 14 to 30 in. diam, 8 threads per in.

American National straight pipe threads have a pitch of $D - (0.05D + 1.1)p + \frac{1}{16}L_1$. See Table 11 for values of L_1. *Couplings with straight internal threads* may be used for ordinary pressures; taper threads should be used for high pressures.

Foundation bolts may be made to the forms shown in Figs. 20 to 22. The difficulty in replacing such bolts as may become broken or injured in service causes the form shown in Fig. 20 to be favored whenever it can be used. $l \geq 5d$.

The S.A.E. Standard for Bolts and Nuts is shown in Fig. 23, proportions of bolts made to this standard being given in Table 23.

All dimensions in inches. **$1/p$ = number of threads per inch.** All heads and nuts to be semifinish. Material—steel **of not less than 100,000 lb** tensile strength and not less than 60,000 lb elastic limit. **These threads not to be used in** cast iron, brass, or aluminum.

Coach and lag screws as shown in Fig. 24 are made to the proportions given in Table 24.

Wood screws are made in lengths from 1/4 to 5 in. for steel and from 1/4 to 3 1/2 in. for brass screws, increasing by 1/8 in. up to 1 in., by 1/4 in. up to 3 in., and by 1/2 in. up to 5 in. **The American National Standard sizes** are given in Table 25. Screws are made with flat, round, or oval heads.

Wrench head bolts and nuts and wrench openings have been standardized by the A.S.A. The **wrench openings** selected are given in Table 14.

Regular nuts (rough, semifinished, and finished) have a maximum width across flats of $1\frac{1}{2}D$ except for $D = \frac{1}{4}$ to $\frac{5}{16}$ when the width $= 1\frac{1}{2}D + \frac{1}{16}$. D is bolt diameter. Tolerance for width is $-0.050D$. Thickness is $\frac{7}{8}D$.

Materials, Strength, and Service Adaptability of Machine Bolts and Screws

The materials to be used for bolts, screws, and nuts depend on service conditions and relative costs. The stresses to be allowed in determining the proportions in any case depend on the nature of the loading and the material.

As a guide to the selection of **bolts and nuts for fastenings** in stationary machinery, the specifications of the Bureau of Steam Engineering of the U. S. Navy are given in Table 29.

The American Screw Co's machine-screw standards are in Table 21.

bolt depends on its relative tightness, the tighter bolts carrying the greater loads. When the conditions of attendance are such as to occasion a great difference in tightness, lower working stresses must be used in designing the bolts than otherwise are necessary. On the other hand, it may be desirable to have the bolts the weakest part of the machine, since their breakage from overload in the machine will result in a minimum cost of replacement. In such cases, the breaking load of the bolts may well be equal to the load which causes the weakest member of the machine connected to be stressed up to the elastic limit.

Table 31. Safe Loads for U. S. Standard Bolts

Bolts screwed up tight have an initial stress due to the tightening before any external load is applied to the machine member. According to Prof. Barr, the initial tensile load due to screwing up for a tight joint varies about as the diameter of the bolt, and may be estimated at 16,000 lb per in. of diameter. There is consequently danger of excessive stresses for bolts of less than

Setscrews for fastening collars and the like to shafting may have forms of heads and points as shown in Figs. 16, 17, and 18.

The round point will be found to give better service, since it will not work loose under repeated load application.

The **safe holding power** P of cup or flat-point setscrews (B. H. D. Pinckney, *Am. Mach.*, Oct. 15, 1914) may be calculated from P (lb) $= 63{,}025N/nr$, where N = hp transmitted, n = rpm, and r = radius of shaft, in. Values of P for various diameters d of set screws are as follows:

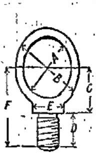

FIG. 15. Eyebolt.

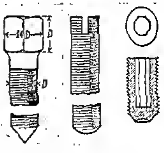

FIG. 16. FIG. 17. FIG. 18. Set Screws.

d (in.) =	1/4	5/16	3/8	7/16	1/2	9/16	5/8	3/4	7/8	1	1 1/8	1 1/4
P (lb) =	100	168	256	368	500	658	840	1,280	1,830	2,500	3,288	4,198

Thus, for a pulley transmitting 6 hp at 300 rpm on a 2 in. shaft, $P = 63{,}025 \times 6/(300 \times 1) = 1{,}260$ lb, indicating the use of either one 3/4 in. screw or two 9/16 in. screws.

Lock nuts and special devices to prevent bolts and nuts from coming loose as may result when vibrations are encountered may be made as shown in Fig. 19. In the type shown in Fig. 19*f*, the thicker nut is shown at the top; since practically the whole load is taken by the upper nut it is considered

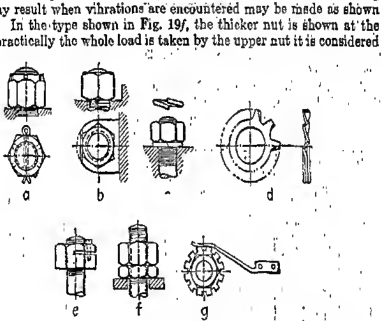

FIG. 19.—Lock Nuts.

good practice to put the thinner nut next to the work and the thicker one on top. Lock washers for bolts (Fig. 19*c*) have been standardized by the S.A.E. (see 1939 Handbook) as follows:

Bolt diameter, in.	1/4	3/8	1/2	5/8	3/4
Washer, width × thickness	5/32 × 1/16	1/8 × 3/32	11/64 × 1/8	13/64 × 5/32	1/4 × 3/16
Bolt diameter, in.		7/8	1	1 1/4	1 1/2
Washer, width × thickness		17/64 × 3/16	5/16 × 1/4	7/16 × 1/4	1/2 × 5/16

An efficient type of lock washer (Fig. 19*d*) made by the Shakeproof Lock Washer Co., forces teeth to dig into the work and nut, resisting thereby any tendency to unscrew because of vibration. The dimensions are as follows:

Table 34 gives tap drill sizes for taps with American (National) Standard, "V," and Whitworth threads.

15/32	1 1/16	57.5	2 1/2	1 5/8	T.P.	68.5	3 3/8	1 5/8	2 1/8
1/2	1 1/16	56.7	2 1/2	1 5/8	S.R.	68.5	3 3/8	1 5/8	2 1/8

should be 3 times the rivet diameter. Frequently, angle connections such as shown in Fig. 38 are used. In such construction, it is good practice to

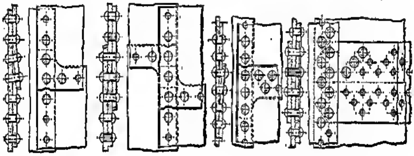

FIG. 33. FIG. 34. FIG. 35. FIG. 36.
Forms of Riveted Joint at Junction of Three or Four Plates.

have the rivet diameter $d = 2 \times$ plate thickness t and the dimension $a = \frac{1}{2}(w - t_1)$, in which w = width of angle leg and t_1 = thickness of leg = $t + \frac{1}{16}$ in. The other dimensions in the figure are in terms of t.

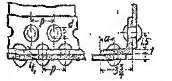

FIG. 37. FIG. 38.
Joining Plates at Right Angles.

Straining Actions in Riveted Joints. The straining actions to which the several elements of a riveted joint are subjected are easily determined as to kind, but are most difficult to evaluate. *More particularly is this true when* the joint is one of several in a structure such as a boiler and receives its load according to the elasticity of the parts through which these loads are transmitted. Without regard to the friction between the plate and assuming all rivets in the joint to be equally well fitted and consequently sharing equally

Table 29. Materials for Bolts and Nuts

Class	Material	Minimum tensile strength, lb per sq in.	Minimum elastic limit, lb per sq in.	Minimum elongation in 8 in. percent	Maximum percentage of	
					Phosphorus	Sulphur
A	Open-hearth nickel or carbon steel	75,000	40,000	23	0.04	0.03
B	Open-hearth carbon steel	58,000	30,000	28	0.04	0.03

Bending Tests. Class A material must bend cold after quenching about an inner diameter equal to the thickness of the test piece in each case without cracking; quenching temperature, 80 to 90 F. For Class B, the same test applies, except that inner diameter equals one-half thickness of test piece.

Hammer Test. Class A material must flatten out cold to one-half the original diameter without showing cracks. Class B must flatten out while heated to a cherry red in daylight to a thickness equal to one-third the original diameter without showing cracks.

Bolts requiring unusual strength are made from material specified under forgings in Table 30. Connecting-rod bolts, for example, are made from "high-grade forgings." For the S.A.E. specifications, see p. 559.

Setscrews may be made from the following material recommended by the Carnegie Steel Co.: carbon, 0.15 to 0.20 percent; manganese, 0.6 to 0.8 percent; phosphorus, not over 0.06 percent; sulphur, 0.06 percent.

Safe loads in tension for U. S. Standard bolts, as determined by Harvey D. Williams, of the Bureau of Steam Engineering, U. S. Navy, are given in Table 31. Colvin and Stanley ("American Machinists' Handbook") compute the tensile and shearing strengths as given in Table 32.

Table 30. Steel Forgings for Bolts

Class	Material	Treatment	Minimum tensile strength, lb per sq in.	Minimum elastic limit, lb per sq in.	Minimum elongation in 2 in., percent	Maximum percentage of		Cold bend about an inner diam of
						phosphorus	sulphur	
High grade..	Open-hearth nickel steel	Anneal and oil-temper	95,000	65,000	21	0.06	0.04	1 in. through 180 deg
A......	Open-hearth nickel or carbon steel	Anneal; oil tempering optional	80,000	50,000	25	0.06	0.04	1 in. through 180 deg
B......	Open-hearth carbon steel	Anneal	60,000	30,000	30	0.06	0.04	½ in. through 180 deg

General Notes on the Design of Bolts

Bolts subjected to shock and sudden change in load are found to be more serviceable when the body of the bolt is turned down or drilled to the area of the root of the thread. The drilled bolt is stronger in torsion.

When a **number of bolts are employed in fastening** together two parts of a machine, such as a cylinder and cylinder head, the load carried by each

Table 38. Dimensions of Quadruple-riveted Butt Joints (Steel Rivets in Steel Plates)

(All dimensions in inches. Letters refer to Fig. 32. Dimensions based on the tensile and shearing strengths given for Table 36.)

1 in. diam. If the bolt is manifestly more yielding than the connected members, it should be designed simply to resist the initial tension or the external load, whichever is the greater. If the probable yielding of the bolt is 50 to 100 percent of that of the connected members, take the resultant stress as the initial tension plus one-half the external load. If the yielding of the connected members is probably 4 to 5 times that of the bolt (as when certain packings are used), take the resultant stress as the initial tension plus three-fourths the external load.

In any given machine, the bolts and screws used should be of as few sizes as possible in order to reduce the number of spanners required to tighten them and the number of drill and tap sizes needed in manufacture.

In drilling and tapping cast iron for studs, it is necessary to tap to a depth equal to 1 1/2 times the stud diameter in order that the strength of the cast-iron threads in shear may equal the tensile strength of the bolt. Drill sizes and depths of hole and thread are given in Table 33.

Table 33. Depths to Drill and Tap Cast Iron for Studs

Diam of stud, in......	1/4	5/16	3/8	7/16	1/2	9/16	5/8	3/4	7/8	1

It is not good practice to drill holes to be tapped through the metal into pressure spaces, as the leakage resulting, even though the bolt fits tightly, will occasion much trouble.

Drill Sizes for American (National) or A.S.M.E. Standard Thread Taps. Diameter of drill = outside diameter of stud *minus* pitch of thread.

cheaper, is objectionable. Further, the holes in different plates cannot be spaced with sufficient accuracy to register perfectly on being assembled. If the hole is punched out say $\frac{1}{16}$ in. smaller than is required and then reamed to size, the metal injured by cold flow during punching will be removed. Annealing after punching also largely obviates the injury. Drilling, while more expensive, permits of greater accuracy and does not injure the metal. The Massachusetts Boiler Inspection Law states: "Rivet holes, excepting for attaching stays or angle bars to heads, shall be drilled full size with plates, butt straps, and heads bolted up in position; or they may be punched not to exceed ¼ in. less than full size for plates over $\frac{5}{16}$ in. in thickness, and ⅛ in. less than

full size for plates not exceeding $\frac{5}{16}$ in. in thickness, and then drilled or reamed to full size with plates, butt straps and heads bolted up in position." The U. S. Navy Department specifies that all holes in boiler plates must be drilled with the plates in place. In structural work, the holes are generally punched for shop riveting, while for field riveting it is usual to drill them to a template, or, if punched, to ream them with the parts to be connected bolted in place.

The tensile strength of the metal between holes drilled in a plate has been found to be greater than that of an undrilled plate. For the spacings usual in riveted work, the increase in strength as shown by experiment is 10 to 12 percent. Punching, on the other hand, results in a loss of tensile strength, experiments showing the strength of the metal between the holes to be 5 to 20 percent under that of unpunched plates in the case of iron, and 8 to 35 percent in the case of steel plates. With the latter, the loss increases with the thickness of the plate.

Hand-riveted joints are of practically the same strength as those machine-riveted, but the load at which visible slip occurs is much greater with machine riveting. In hot riveting, pressures up to 150,000 lb per sq in. and even higher are used, and in cold riveting the pressure required is about 300,000 lb per sq in. of rivet section. Where the pressure exceeds 225,000 to 270,000 lb,

Forms and Proportions of Riveted Joints for Boilers and Tanks. Riveted joints for steam boilers and tanks may have the forms and proportions recommended by the Hartford Steam Boiler Inspection and Insurance Co., as given in Figs. 29 to 32, and Tables 35 to 38.

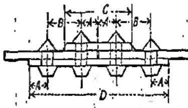

FIG. 30.

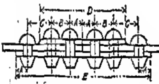

FIG. 31.

FIG. 32.

FIGS. 29–32.—Forms of Riveted Butt Joints.

Lap-riveted Joints for Girth Seams of Cylindrical Vessels with Unstayed Heads

In horizontal tubular boilers, tanks, and similar vessels, it is customary for the sake of convenience to use the same size of rivets in the girth seams as in the longitudinal seams. Where the heads of such vessels are not stayed by tubes or through braces, the strength of the circumferential joints should be at least 50 percent of that required for the longitudinal joints of the vessel. The joints in the table below are designed to meet the above requirements, and it should be understood that a higher efficiency could be obtained in some instances by using a different size of rivets. It is assumed in each case that the efficiency of the corresponding longitudinal joint is not greater than that of the quadruple-riveted butt joints of Table 38.

The form of the **joint at the junction of three or four plates** may be as shown in Figs. 33 to 36.

When **plates are to be joined at right angles** and riveted, the joint may have the form shown in Fig. 37. With such joints, the outer radius of curvature of the plate should be at least 4 times the plate thickness. The overlap

Woodruff keys (Fig. 41) are made by the Whitney Mfg. Co., Hartford, Conn., in the sizes given in Table 40, and for use with shafts not larger than 2½ in. diam. *The S.A.E. Standards should also be consulted. Cutters for* milling out the key seats, as well as special machines for using the cutters, are to be had from the manufacturer. Where the hub of the gear or pulley is relatively long, two keys should be used. Slightly rounding the corners or ends of these keys will obviate any difficulty met with in removing pulleys from shafts. They are not to be used as sliding keys or feathers.

Gib-head Keys (Fig. 42). This form of taper key is necessary when the smaller end is inaccessible for drifting out and the larger end is accessible. It can be used with care with all sizes of shafts. Its use is forbidden in certain jobs and places for safety reasons. Proportions are given in Table 41.

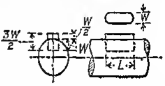

Fig. 43.—Sunk Key.

Sunk keys are made by the Pratt & Whitney Co., of Hartford, Conn., to the form and dimensions given in Fig. 43 and Table 43. These keys are particularly adapted to the case of hubs fitting adjacent parts such that neither end of the key is accessible. The difficulties attending the sinking of keyways for these keys have militated against their frequent use. The Pratt & Whitney Co., however, has devised a successful spline miller which greatly facilitates this ordinarily troublesome operation.

Feather keys are used to prevent parts from turning on a shaft while allowing them to move in a lengthwise direction. They may be of the forms shown in Fig. 44, with dimensions as given in Table 43.

in taking up load, the accepted method of analyzing the stresses in the joint is as follows:

Let t = thickness of plate, in. d = diameter of rivet, in. p = pitch of rivets, in. n = number of rivets per pitch width of plate, in single shear. m = same, in double shear. f_t = intensity of stress in tension, lb per sq in. f_c = intensity of stress in crushing, lb per sq in., single shear. f_s = intensity of stress in shearing, lb per sq in., single shear (f'_c and f'_s for double shear). P = pressure existing in the tank or boiler, lb per sq in. D = internal diam

the proportions (see Fig. 48) $w = 0.241D$; $h = 0.075D$; $d = 0.850D$: for sliding when not under load, $w = 0.241D$; $h = 0.125D$; $d = 0.750D$. For **six-spline fittings**, $w = 0.25D$ and for permanent fit $h = 0.05D$; $d = 0.90D$: for sliding when not under load, $h = 0.075D$; $d = 0.85D$: for sliding when under load, $h = 0.10D$; $d = 0.80D$. **For ten-spline fittings**, $w = 0.156D$ and for permanent fit $h = 0.045D$; $d = 0.91D$: for sliding when not under load,

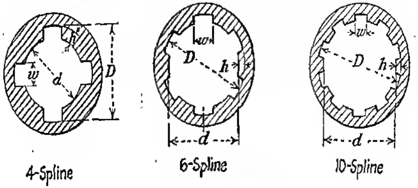

Fig. 48.—Splined Shaft.

$h = 0.07D$; $d = 0.86D$: for sliding when under load $h = 0.095D$; $d = 0.81D$. **For sixteen-spline fittings**, $w = 0.098D$ and for permanent fit $h = 0.045D$; $d = 0.91D$: for sliding when not under load, $h = 0.07D$; $d = 0.86D$: for sliding when under load, $h = 0.095D$; $d = 0.81D$.

***Taper pins** are sometimes used in transmitting very small torques,* and may be placed in either of the ways shown in Fig. 47. They should be fitted so that the parts are drawn together, when the pin is driven home, to prevent their working loose.

Table 45. Morse Standard Taper Pins

Length	$\frac{3}{4}$–$1\frac{1}{4}$	$\frac{3}{4}$–2	$\frac{3}{4}$–$2\frac{1}{4}$	$\frac{3}{4}$–3	$\frac{3}{4}$–3	$\frac{3}{4}$–3	$\frac{3}{4}$–4	1–4	$1\frac{1}{4}$–$4\frac{1}{4}$	$1\frac{1}{2}$–$5\frac{1}{4}$	$1\frac{1}{2}$–6

The Groov-Pin Corp., New Jersey, have developed a special **grooved pin** which may be used instead of taper pins in certain cases.

Cottered joints may be employed for fastening rods to other rods, rods to pistons and cross heads, yokes to rods (as in the case of connecting rods), and for services of similar kinds. Some forms of such joints and proportions recommended are shown in Figs. 49–52.

The preceding equations may be used to determine the efficiency of any form of riveted joint of known dimensions. When designing, the most economic relations between the pitch and diameter of rivet and the thickness of plate obtain when the three efficiencies are equal. If then these be equated and solved for p, d, and t, it will be found that, for the **longitudinal seams** of boilers and tanks,

$$t = PD(nf_c + mf'_c + f_t)/2(nf_c + mf'_c)f_t$$
$$d = 4(nf_c + mf'_c)t/\pi(nf_s + 2mf'_s)$$
$$p = [\pi d^2(nf_s + 2mf'_s)/4tf_t] + d$$

A factor of safety of 5 or 4½ is used in determining the value of t.

For iron plates and rivets, $f_s = 38{,}000$, $f_c = 65{,}000$, $f'_s = 35{,}500$, $f'_c = 80{,}000$; for steel plates and rivets, $f_s = 44{,}000$, $f_c = 90{,}000$, $f'_s = 45{,}000$, $f'_c = 110{,}000$; $f_t = 40{,}000$ for iron and 55,000 for steel.

For the **girth seam** of single- or double-riveted lap joints, since the thickness of plate and diameter of rivets are established (all holes being of the same diameter for economy in fabrication), the pitch is determined such that a sufficient number of rivets may be placed to take up the total load on the joint with the proper limits of stress in shear and compression. The total load on the rivets in a girth seam is equal to $\pi D^2P/4$. The equations for t, d, and p will be found to give proportions ensuring steamtightness up to pressures of 200 lb per sq in. when joints are properly calked.

The following **general practice rules** will also be found to be serviceable:

1. Butt joints are to be preferred to lap joints, since the latter occasion severe bending stresses in the rivet, which is a most frequent cause for failure.
2. The distance from the center line of the row of rivet holes nearest the edge of plate to edge of plate should be 1½ to 2 times rivet diameter.
3. The rivet diameter should be $d = 1.2\sqrt{t}$ to $1.4\sqrt{t}$.

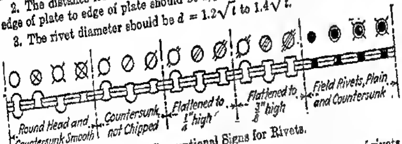

FIG. 39.—Conventional Signs for Rivets.

4. In multiple-riveted joints, the minimum distance between rows of rivets is 1.7d or 0.6 to 0.8 pitch for staggered riveting. For chain riveting, this should be at least 2d and preferably 2½d.

Materials Specifications for Rivets and Plates. See pp. 577–581. A factor of safety of 4½ to 5 is usually employed for boiler joints.

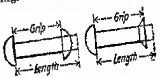

FIG. 40.

Conventional signs to indicate the form of the head to be used and whether the rivet is to be driven in the shop or the field at the time of erection are given in Fig. 39. The lengths of rivets for various grips are given in Table 39 (see also Fig. 40).

Punched vs. Drilled Plates. Holes in plates forming parts of riveted structures are punched, punched and reamed, or drilled. Punching, while

space between mating parts. **Tolerance** is defined as the amount of variation permitted in the size of a part.

Loose Fit (Class 1), Large Allowance. This fit provides for considerable freedom and embraces certain fits where accuracy is not essential, such as machined fits of agricultural and mining machinery; controlling apparatus for marine work; textile, rubber, candy, and bread machinery; general machinery of a similar grade; some ordnance material.

Free Fit (Class 2), Liberal Allowance. For running fits with speeds of 600 rpm or over and journal pressures of 600 lb per sq in. or over. For dynamos, engines, many machine-tool parts, and some automotive parts.

Medium Fit (Class 3), Medium Allowance. For running fits under 600 rpm and with journal pressures less than 600 lb per sq in.; also for sliding fits and the more accurate machine-tool and automotive parts.

Snug Fit (Class 4), Zero Allowance. This is the closest fit which can be assembled by hand and necessitates work of considerable precision. It should be used where no perceptible shake is permissible and where moving parts are not intended to move freely under a load.

Wringing Fit (Class 5), Zero to Negative Allowance. This is also known as a **tunking fit** and is practically metal-to-metal. Assembly is usually selective and not interchangeable.

Tight Fit (Class 6), Slight Negative Allowance. Light pressure is required to assemble these fits, and the parts are more or less permanently assembled, such as the fixed ends of studs for gears, pulleys, and rocker arms. These fits are used for drive fits in thin sections or extremely long fits on very light sections. Used in automotive, ordnance, and general machine manufacturing.

Medium Force Fit (Class 7), Negative Allowance. Considerable pressure is required to assemble these fits, and the parts are considered permanently assembled. These fits are used in fastening locomotive wheels, car wheels, armatures of dynamos and motors, and crank disks to their axles or shafts. They are also used for shrink fits on medium sections or long fits. These fits are the tightest which are recommended for cast-iron holes or external members as they stress cast iron to its elastic limit.

Heavy Force and Shrink Fit (Class 8), Considerable Negative Allowance. These fits are used for steel holes where the metal can be highly *stressed without exceeding its elastic limit. They cause excessive stress for* cast-iron holes. Shrink fits are used where heavy force fits are impractical, as on locomotive wheel tires and heavy crank disks of large engines.

Allowances and Tolerances for Various Fits

The formulas for allowances and tolerances for the various fits enumerated above, as recommended tentatively by the A.S.A., are given in Table 46. These are based on good practice or, where this varies, a compromise is used. The tolerances on holes apply only to reamed holes or those having a finish equivalent to reaming. It should be noted that, in practice, to cut down cost, as large a tolerance should be allowed as possible, all factors being considered. In classes (5) to (8), selective assembly is usually required, *i.e.*, a large shaft must be used with a large hole, and vice versa.

In Table 47 is given a summary of the allowances, allowances plus tolerance, and average interferences for the various classes of fits, as recommended tentatively by the A.S.A. **Interference** here denotes negative allowance.

however, there is danger that the lateral pressure of the rivet may crack the plate.

Frictional Resistance of Riveted Joints. *Rivets in cooling contract* longitudinally and draw the plates together with considerable force. They also contract laterally and therefore do not completely fill their holes when cold. Before shearing can take place, it is consequently necessary that the plates shall slip on each other, such slipping, however, being resisted by the friction of the surfaces in contact. According to C. Bach, this frictional resistance when slipping begins ranges from 14,000 to 30,000 lb per sq in. of rivet section at each pair of surfaces in contact. As any appreciable slip of a boiler joint will result in leakage, it is the practice of European engineers to design such joints according to rules based by Bach on the resistance to slipping. The proportions specified in these rules, however, do not differ greatly from those based on a consideration of shearing strength.

KEYS, PINS, AND COTTERS

Square and flat plain taper keys have the same dimensions as gib-head keys (Table 41) up to the dotted line of Fig. 42.

Saddle keys and flat keys (Fig. 45) are used only for the transmission of small torques or turning efforts that are never liable to sudden changes in magnitude. Under excessive stresses, they turn around the shaft and damage it.

In transmitting large torques, it is customary to use two or more keys, as shown in Fig. 46. The arrangement shown at (*a*) permits more ready cutting of the keyway. If but one key is used with the arrangement shown at (*b*), torque can be taken only in one direction.

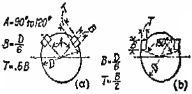

Fig. 46.—Double-keying of Shafts.

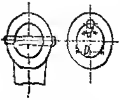

Fig. 47.—Taper Pins.

Splined shafts have been standardized by the S.A.E. (*S.A.E. Handbook*) for 4-, 6-, and 10-spline fittings. **Four-spline fittings** for permanent fit have

Cast-iron Hub on Steel Shaft. Where the shaft is solid, or hollow with an inside diameter not over 25 percent of the outside diameter, Fig. 57 may be used to determine maximum tensile stresses in the cast-iron hub, resulting from the press-fit allowance; for various ratios d/D, Fig. 58 gives the press-fit pressures. These curves are based on a modulus of elasticity of 30×10^6 lb per sq in. for steel and 15×10^6 for cast iron. For a hollow shaft with an inside diameter more than about ¼ the outside, the Lamé formulas may be used.

Pressure Required in Making Press Fits. The force required to press a hub on the shaft is given by $\pi fpdl$ where l is length of fit, p the unit press-fit pressure between shaft and hub, f the coefficient of friction, and d the shaft diameter. Values of f varying from 0.03 to 0.33 have been reported, the lower values being due to yielding of the hub as a consequence of too high a fit allowance; the average is around 0.10 to 0.15. (Horger and Nelson, *Jour. of Applied Mechanics*, March, 1938.)

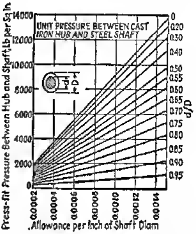

Fig. 58.—Press-fit Pressures between Cast-iron Hub and Shaft.

Torsional Holding Ability. The torque required to cause complete slippage of a press fit is given by $T = \frac{1}{2}\pi fpld^2$. Local slippage will usually occur near the end of the fit at much lower torques. If the torque is alternating, stress concentration and rubbing corrosion will occur at the hub face so that, eventually, fatigue failure may occur, at considerably lower torques. Only in cases of static torque application is it justifiable to use ultimate torque as a basis for design.

SHAFTS, AXLES, CRANKS

(For critical speeds of shafts see pp. 514–518, and for torsion of shafts of various cross sections, see Table 11, p. 478.

Strength of Shafting. Shafts may be subjected to torsion, to bending, to axial tension or compression, or to a combination of any or all of these actions. To determine the stress set up in shafts when subjected to these actions, let d = diameter of shaft, in.; T = torque moment, in.-lb; M = bending moment, in.-lb; S = normal stress in shaft, lb per sq in.; S_s = shearing stress in shaft, lb per sq in.; hp = horsepower transmitted; N = rpm of shaft. Then for solid circular shafts under pure torsion,

$$d = \sqrt[3]{5.1T/S_s} = 68.5\sqrt[3]{\text{hp}/NS_s}$$

Strength of Shafts under Combined Torque and Bending. Where shafts are subjected to combined bending and twist, the maximum resultant shearing stress is given by

$$S_s = 5.1\sqrt{M^2 + T^2}/d_1{}^3 \qquad \text{or} \qquad d = \sqrt[3]{5.1\sqrt{M^2 + T^2}/S_s}$$

Example. A 2½ in. round shaft carries a 30 in. pulley weighing 500 lb. The total pull of the belt is 2,000 lb, and the unbalanced pull is 1,500 lb horizontally. Pulley is 6 in. from hanger.

Resultant force acting on shaft $= \sqrt{500^2 + 2000^2} = 2{,}060$ lb. $M = 2060 \times 6 =$ 12,360 in.-lb at hanger, $T = 1500 \times 15 = 22{,}500$ in.-lb. From the preceding formula, $S_s = (5.1/15.625)\sqrt{12{,}360^2 + 20{,}500^2} = 8{,}400$ lb per sq in.

An analysis of the straining action in cotter joints which will serve as a guide in the determination of proportions for such joints in general may be made with reference to the type of joint shown in Fig. 53. The joint may fail in any one of the following ways, and the relation between load and stress is as specified. Let F = load on rod, lb;

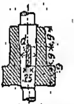

FIG. 49.

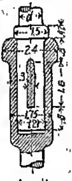

FIG. 50.

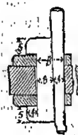

FIG. 51.

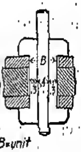

FIG. 52.

Cottered Joints.

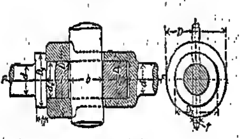

FIG. 53.—Cottered Joint.

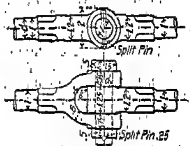

FIG. 54.—Knuckle Joint.

d = diam of rod, in.; f_t, f_s, and f_c the tensile, shearing, and crushing stresses, lb per sq in. Then (for wrought-iron rods),

1. Failure of rod by tension: $F = (\pi d^2/4) f_t$ (1)
2. Tearing of rod end across the cotter hole: $F = [(\pi d_1^2/4) - d_1 t] f_t$. (2)
   Equating (1) and (2) and letting $t = d_1/4$, then $d_1 = 1.21d$ and $t = 0.3d$.
3. Tearing of socket across the hole: $F = [\pi/4(D_2^2 - d_1^2) - (D_2 - d_1)t] f_t$, whence (allowing for clearance), $D_2 = 1.75d$.
4. Double shearing of cotter: $F = 2btf_s$, whence
   $$b = d_1(f_t/f_s) = 1.6d \text{ (approx) for iron and steel}$$
5. Crushing the cotter bearing surface in rod end: $F = d_1 t f_c$.
6. Crushing the cotter bearing surface in socket: $F = t(D - d_1) f_c$.
7. Shearing socket end: $F = 2[l(D - d_1) f_s]$. $(D = 2d_1)$
8. Shearing rod end: $F = 2l_1 d_1 f_s$. (Let $f_s = \frac{1}{2} f_s$ because of grain.)
   Letting $l = l_1$, then $l = 0.65d$, say, $l = 0.75d$.
9. Crushing collar on rod: $F = (\pi/4)(D_3^2 - d_1^2) f_c$, whence $D_3 = 1.4d$, say 1.5d.
10. Shearing collar off rod: $F = \pi d_1 t_1 f_s$, whence $t_1 = 0.42d$, say, 0.5d.

When two rods are to be joined so as to permit movement at the joint, a round pin is used in place of a cotter. In such cases, the proportions may be as shown in Fig. 54.

SHRINK, PRESS, DRIVE, AND RUNNING FITS

Classification of Fits. The A.S.A. tentatively recommends the following classification of fits. **Allowance** is defined as the minimum clearance

it is recommended that the above stresses be reduced 25 percent and where failure of the shaft would be a serious matter an additional 25 percent reduction in stress is proposed.

Charts based on the above formulas and given in the A.S.A. tentative codes for determining the necessary diameters of shafting subjected to combined torsion and bending or to simple torsion or simple bending are given in Figs. 59 and 60. These charts have as ordinates K_mM and as abscissas K_tT at the bottom or K_tP at the top where P is the horsepower

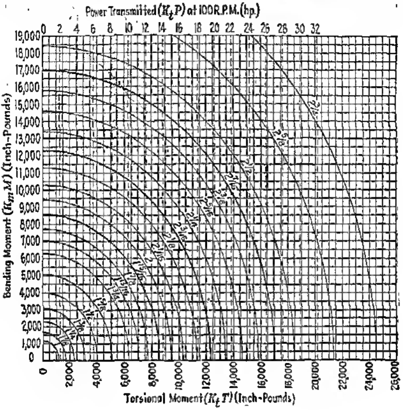

Fig. 59.

transmitted at 100 rpm corresponding to the torque T. To find the shaft diameter, it is necessary to find the intersection of the ordinate representing the bending moment K_mM with that representing the torque K_tT or the horsepower K_tP transmitted at 100 rpm. These values of shaft diameter are based on a stress of 6,000 lb per sq in.; to find the value at any other stress S_s, it is necessary to multiply the diameter obtained from the chart by $\sqrt[3]{6{,}000/S_s}$. The light arcs in the chart indicate standard sizes of machinery shafting; the heavy arcs indicate standard sizes of transmission shafting.

Example. A shaft is subjected to a maximum torsional moment of 6,900 in.-lb combined with a maximum bending moment of 11,500 in.-lb. The loads are steady, stress concentration is negligible, and the material has an elastic limit in tension of 27,000 lb per sq in. Taking 30 percent of this value, we obtain 8,000 lb per sq in. as the working stress. Since the loads are steady from Table 49, $K_m = 1.5$ and $K_t = 1$. Using the chart of Fig. 59 for $K_tT = 6{,}900$ and $K_mM = 17{,}200$, we get $d = 2.5$ in. This value given by the chart is for a stress of 6,000 lb per sq in. For a stress of 8,000

These fits are not intended to cover all work, since individual conditions may make changes necessary from the standard. However, it is believed they will apply to the majority of cases arising in practice.

Table 46. Formulas for Recommended Allowances and Tolerances

Class of fit	Method of assembly	Allowance	Selected average interference of metal	Hole tolerance	Shaft tolerance
(1) Loose	Strictly interchangeable	$0.0025\sqrt[3]{d^2}$	....	$0.0025\sqrt[3]{d}$	$0.0025\sqrt[3]{d}$
(2) Free	Strictly interchangeable	$0.0014\sqrt[3]{d^2}$	....	$0.0013\sqrt[3]{d}$	$0.0013\sqrt[3]{d}$
(3) Medium	Strictly interchangeable	$0.0009\sqrt[3]{d^2}$	....	$0.0008\sqrt[3]{d}$	$0.0008\sqrt[3]{d}$
(4) Snug	Strictly interchangeable	0.0000	....	$0.0006\sqrt[3]{d}$	$0.0004\sqrt[3]{d}$
(5) Wringing	Selective assembly	....	0.0000	$0.0006\sqrt[3]{d}$	$0.0004\sqrt[3]{d}$
(6) Tight	Selective assembly	....	$0.00025d$	$0.0006\sqrt[3]{d}$	$0.0006\sqrt[3]{d}$
(7) Medium force	Selective assembly	....	$0.0005d$	$0.0006\sqrt[3]{d}$	$0.0006\sqrt[3]{d}$
(8) Heavy force or shrink	Selective assembly	....	$0.001d$	$0.0006\sqrt[3]{d}$	$0.0006\sqrt[3]{d}$

Comparison of Shrink and Force Fits. Shrink fits are used in places where a force fit would be difficult to assemble, as for example, locomotive wheel tires. On the other hand, the convenience of assembling force fits makes their use advantageous in cases where a hydraulic press of sufficient capacity is available for this purpose. Force fits are sometimes made with the mating parts slightly tapered. This taper, while making the fit easier to assemble, has the disadvantage of making the fit less reliable since, if looseness develops, a slight axial movement serves to allow complete looseness between the parts. This disadvantage may be overcome if the tapered portion is allowed to project through the fit, as shown in Fig. 55, so that the part of the shaft in contact with the hub is cylindrical. The tapered end thus serves to make assembling easier.

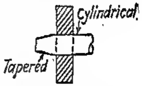

FIG. 55.

C. E. Johansson, Inc., have prepared the following table of tolerances for accurate work. The quantities given are permissible variations above or below the desired dimensions. For less accurate work, these tolerances may be doubled.

Tolerances (+ and −) for Accurate Work

Diam of hole in...	3/64–1/8	9/64–1/4	17/64–27/64	7/16–23/32	47/64–1 3/16	1 13/64–1 57/64
Tolerance, in.....	0.00008	0.00012	0.00017	0.00022	0.00028	0.00034

Diam of hole, in...	1 29/32–2 41/64	2 31/32–4 17/32	4 35/64–6 57/64	6 29/32–10 7/16	10 29/64–15 3/4
Tolerance, in.....	0.00042	0.00050	0.00059	0.00069	0.00079

The allowances which should be made for different kinds of fits are tabulated on p. 792. They are based on the use of the hole as the nominal size and give the amounts by which the shaft should be less than (−) or greater than (+) the nominal hole size. If the shaft is selected as the base, the allowances for the hole will be of the same magnitude but of opposite sign. The per-

limits, thus indicating that the mechanism of fatigue failure is related to the maximum shear theory, a more rational procedure is to design the shaft on the basis of the maximum shear theory.

CASE 1. Assume that a *pure torque* T consisting of a constant torque T_c on which is superimposed a variable torque T_v is acting on the shaft. Using the equations for working stress given by Soderberg (*Jour. Applied Mechanics*, Sept., 1935), the required diameter is given by

$$d = \sqrt[3]{\frac{32F_s}{\pi}\left\{\frac{KT_v}{S_e} + \frac{T_c}{S_y}\right\}}$$

where F_s = factor of safety (frequently taken as between 2 and 3); K = factor of stress concentration in torsion (see pp. 420–425 for values of K); S_e = endurance limit of material in reversed bending; S_y = yield stress in tension.

CASE 2. Assume the shaft is subject to *pure bending* only, consisting of a constant component of bending moment M_c on which is superimposed a variable component M_v. *The equation for required diameter is likewise*

$$d = \sqrt[3]{\frac{32F_s}{\pi}\left\{\frac{M_c}{S_y} + \frac{KM_v}{S_e}\right\}}$$

In this case, the factor K is the stress concentration factor in bending (see pp. 420–425). The stress concentration effect may be due to fillets, keyways, bearing fits, etc.

CASE 3. For the usual case of *constant torque T and reversed bending moment M*, the shaft diameter is obtained from

$$d = \sqrt[3]{\frac{32F_s}{\pi}\sqrt{\left(\frac{KM}{S_e}\right)^2 + \frac{T^2}{S_y^2}}}$$

In this case, K is the stress concentration factor in bending.

Examples. A shaft is subjected to an alternating bending moment M of 12,000 in.-lb and a constant torque T of 6,000 in.-lb. Assume that at the point of maximum bending moment there is a press fit for which the stress concentration factor is 2.5. The yield stress S_y = 36,000, and the endurance limit S_e in reversed bending is 30,000 lb per sq in. The factor of safety F_s is to be taken as 2. Since these are the conditions of Case 3, substitution in the formula for this case gives

$$d = \sqrt[3]{\frac{32 \times 2}{\pi}\sqrt{\left(\frac{2.5 \times 12{,}000}{30{,}000}\right)^2 + \left(\frac{6000}{36{,}000}\right)^2}} = 2\tfrac{3}{4} \text{ in.}$$

Stiffness of Shafting. Stiffness of shafting may become important where critical speeds, vibration, etc., may occur. Moreover, through lack of proper stiffness, much trouble may arise in upkeep of bearings. Therefore, in addition to determining the strength of shafting by the above methods, it is also necessary to check up on the stiffness. In practice, the angular twist of shafting is usually limited to 1 deg per ft of length. For calculating the diameter d required for a given total angular twist a in degrees of a shaft of length l subjected to a torque T, or horsepower hp at N rpm, the following formula may be used (G being the modulus of rigidity):

$$d = 4.9\sqrt[4]{Tl/aG} = 77.6\sqrt[4]{\text{hp} \times l/NaG}$$

It should be noted that alloy-steel shafting is no stiffer than ordinary carbon-steel shafting, the stiffness being proportional to the modulus of elasticity which does not change much for different steels.

equivalent stress given above is based on the maximum shear theory and is numerically equal to the radial fit-pressure added to the tangential tension in the hub. Where the shaft is hollow, with an inside diameter equal to more than about 25 percent of the outside diameter, the allowance in inches per

[1] (+) denotes clearance or amount of looseness.
[2] Obtained by fitting or selection.

It is not necessary that both shaft and hole member be made to the same class of fit. For example, shaft members of Class 2 may be used with hole members of Classes 1 and 3, or vice versa.

inch to obtain an equivalent hub stress of 30,000 lb per sq in. may be determined by using Lamé's thick cylinder formulas (*Jour. Applied Mechanics*, Dec., 1937, p. A-185). It should be noted that these curves hold only when the maximum stress is below the yield point; above the yield point, plastic flow occurs and the stresses are less than calculated.

Standard stock lengths for cold-finished shafting are 16, 20, and 24 ft.

Cranks and Crankshafts. Crankshafts may be designed for strength by determining the bending and twisting moments at the weakest sections and combining these in accordance with the methods described above. As an example of this type of calculation, take a crank of the overhung type having the proportions given in Fig. 61 and made of wrought iron or steel. The following formulas apply (neglecting stress concentration):

Bending at section $a - b$: $Fl = tw^2S/6$; $t = 6Fl/w^2S$; $w = \sqrt{6Fl/t^2S}$ where S is the bending stress.

Bending at section $c - e$: $Fx = wt^2S/6$; $t = \sqrt{6Fx/w_1S}$; $w_1 = 6Fx/t^2S$.

Table 50. Horsepower Transmitted by Turned Steel Line Shafting

(Shafting well supported and with pulleys near to the bearings.)

For cold-rolled line shafting (up to 5 in.), add 30 percent. For head shafts of turned steel, *subtract 30 percent. For head shafts of cold-rolled steel, subtract 10 percent.* For transmission shafts (without pulleys) of turned steel, add 80 percent. For transmission shafts (without pulleys) of cold-rolled steel, add 125 percent.

In addition, the stress due to the combined bending and twisting moments at the main journal may be checked up by the use of the charts of Figs. 59 and 60. In these formulas, F = load on crank pin, lb; l and x are lever arms, in. (see Fig 61); w = width of crank web near shaft boss, in.; w_1 = width of crank web near pin boss, in.; t = web thickness, in.; S = allowable stress, lb per sq in. The value of the stress S is commonly taken as 4,500 to 6,000 for wrought iron and steel; this value is low enough to allow for stress concentration effects.

Fundamental methods for calculating the stresses and deformations for **single and multiple-throw crankshafts** are given by Timoshenko and Lessells, "Applied Elasticity," p. 183. The resulting formulas for multiple-throw crankshafts are, however, quite complicated.

For determining **torsional critical speeds** of internal-combustion engines, (see p. 513) it is important to know the stiffness of the crankshafts in torsion.

For hollow shafts, having a given ratio of inside to outside diameter $n = d_1/d_2$, the required diameter may be found by multiplying the required diameter of a solid shaft, as found above, by a factor $\sqrt[3]{1/(1-n^4)}$.

Thus, for a hollow shaft, the required outside diameter is given by

$$d_2 = \sqrt[3]{5.1\sqrt{M^2+T^2}/S_s(1-n^4)}$$

The relative torsional strength of solid and hollow shafts may be determined by means of Table 48.

Examples. What is the diameter of a solid shaft equal in strength to a 10 in. shaft having a 4 in. hole? $d_1/d_2 = 4/10 = 0.40$; for this ratio, $D/d_2 = D/10 = 0.991$, from which $D = 9.91$ in.

Required the outside diameter of a hollow shaft with hole $= 0.6 \times$ outside diameter equal in strength to an 8 in. solid shaft. d_2/D(for $d_1/d_2 = 0.60$) $= 1.047 = d_2/8$, whence $d_2 = 8.38$ in.

Required the dimensions of a hollow shaft but ⅔ the weight of a 12 in. solid shaft of the same strength. Here w = ⅔ = 66.7 percent, for which (from table) $d_1/d_2 = 0.64$ and $d_2/D = 1.063$; hence $d_2 = 12 \times 1.063 = 12.76$ in., and d_1 (from $d_1/12.76 = 0.64$) = 8.16 in.

Table 48. Relative Strengths of Solid and Hollow Shafts

D = diam of solid shaft, d_2 = outside diam of hollow shaft of equal torsional strength, d_1 = inside diam of hollow shaft of equal torsional strength, w = weight of hollow shaft in percentage of the weight of a solid shaft of equal torsional strength,

$$D = \sqrt[3]{(d_2^4 - d_1^4)/d_2}.$$

The tentative **Code for Design of Transmission Shafting** of the A.S.A. recommends that the values of M and T in the preceding formula be multiplied by certain shock and fatigue factors K_m and K_t depending on the service conditions. The formula then becomes

$$d = \sqrt[3]{5.1\sqrt{(K_m M)^2 + (K_t T)^2}/S_s}$$

K_m and K_t are to be taken from Table 49.

Table 49. Values of the Factors K_m and K_t

	K_m	K_t
STATIONARY SHAFTS:		
Gradually applied load	1.0	1.0
Suddenly applied load	1.5–2.0	1.5–2.0
ROTATING SHAFTS:		
Gradually applied or steady loads	1.5	1.0
Suddenly applied loads, minor shocks	1.5–2.0	1.0–1.5
Suddenly applied loads, heavy shocks	2.0–3.0	1.5–3.0

The A.S.A. tentative code recommends that the working stress S_s in the foregoing formula be taken as 30 percent of the elastic limit in tension and not more than 18 percent of the ultimate tensile strength. For commercial steel shafting, this gives 8,000 lb per sq in. without allowance for keyways. Where keyways or fillets are present so as to produce stress concentration,

For marine-engine shafts, see p. 1105. For propulsion shafting, see p. 1432. **Diesel-engine crankshafts** (see p. 1438) should be designed not only for strength but for avoidance of critical speed. (See *Trans. A.S.M.E.*, Applied Mechanics, Vol. 50, No. 8, for methods of calculating critical speeds of Diesel engines.)

Crank disks of cast iron (Fig. 62) may be designed with the following proportions:

$$D_3 = 0.8D \qquad B = \tfrac{3}{4}D \qquad A = \tfrac{5}{8}D \qquad C = \tfrac{1}{4}D$$
$$E = \tfrac{1}{3}D \qquad d_1 = 2d \qquad D_1 = 1\tfrac{3}{4}D \qquad d_2 = 0.8d$$

The arc dimension a varies with the amount of counterweight to be provided.

COUPLINGS AND CLUTCHES

Solid Couplings

Solid couplings do not allow any relative movement between the coupled shafts.

Flange couplings (Fig. 63) are made of a plain face or of male and female type. The proportions are in terms of $k = (d + \tfrac{1}{2})$ in., where d is the shaft

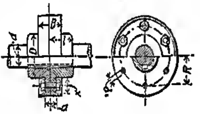

Fig. 63.—Flange Coupling.

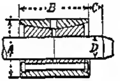

Fig. 64.—Double-cone Compression Coupling.

diameter in inches. $D = d + 0.8k$; $a = 0.55k$; d_1 = bolt diam $= 0.6d/\sqrt{N}$, where N is the number of bolts; $B = 0.55k + 3d_1$; $l = 1.4k$; $R = 1.5d$; $X = 2.5d_1$.

Flange couplings may be purchased for shafts 1 to 10 in. in diameter.

Double-cone compression couplings (Fig. 64) are convenient for connecting two shafts of considerable difference in diameters. Made by P. B. Wood's Sons Co., Chambersburg, Pa., in the sizes of Table 52.

3 7/16	9	13	5 1/4	6 7/16	15 1/4	23 1/4	9 3/4				

Clamp couplings (Fig. 65) are bored with halves separated during boring, to allow for clamping the shafts. Usual dimensions are shown in Table 53.

Ring compression couplings are used for outdoor service where danger of rusting exists. The sleeve is split in two. Proportions are shown in Fig. 66. These couplings are used with shafts up to 6 in. diam.

lb per sq in., $d \times \sqrt[3]{6000/8000} = 2.28$ in., the nearest standard machinery shaft being $2\frac{1}{4}$ in. If the shaft were hollow, this value would have to be multiplied by $\sqrt[3]{1/(1 - n^4)}$ where n is the ratio of outside to inside diameter.

Determination of Maximum Bending Moment. Frequently, the forces acting on the shaft do not act in the same plane. In such cases, the bending moments due to each force must be combined vectorially to get the resultant maximum bending moment M. This value is then used in the formulas or charts given above in combination with the torque moment.

If shafts are subjected to axial tensile or compressive loads, the stresses due to these loads must be superimposed on those due to the bending

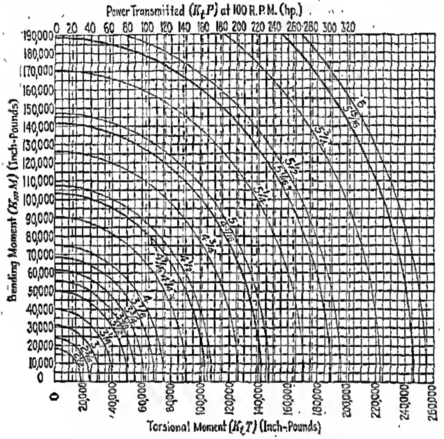

FIG. 60.

moment. These stresses may be thought of as due to an additional bending moment which may be added to the bending moment M used in the above formulas.

Rational Method for Designing Shafting. The preceding method of designing shafting has the disadvantage of basing the design on the properties of the materials under static loading without reference to its fatigue properties or the amount of stress concentration actually present in the shaft. The presence of the empirical factor K_m and K_t makes for further uncertainty. Inasmuch as most failures of shafting are fatigue failures, it is more logical to base the working stress on the endurance limit for the particular range of stress considered. Since test data show that endurance limits in reversed torsion are about half the corresponding bending endurance

made by the De Laval Co. are **given in Table 55.** The normal space between flanges is ⅛ in.

Flexible disk couplings (Fig. 69) consist of two flanges, driving and driven. Both have bolts engaging an intermediate flexible disk transmitting the power. The disk is made of leather, or rubber fabric for smaller sizes; steel laminations are used on some makes (Thomas Flexible Coupling Co., Warren, Pa.). The dimensions and capacities

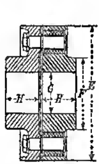

Fig. 68.—Rubber Bushing Coupling.

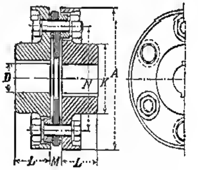

Fig. 69.—Flexible Disk Coupling.

of flexible disk couplings, as made by Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa., are given in Table 56.

The **Grundy flexible coupling** consists of two cast-iron flanges (Fig. 70) and a leather disk. The leather disk has lugs fitting into apertures cast in the flanges. Dimensions and capacities are given in Table 57. The capacities are shown for steady load.

The deflection of shafting is usually limited to 0.01 in. per ft of length. For slow or moderate speed shafts, if the loads acting are known, the deflections may be computed using the ordinary beam formulas. For higher speeds, the effect of centrifugal action enters, so that this method is no longer sufficient. In such cases, the rule for spacing hangers given by Pinkney may be used (see below).

Practical Rules for Proportioning Mill Shafting. In many cases, it is impossible to calculate accurately the loads causing bending and twisting in shafting. Because of this and because of the possibility that additional pulleys may be installed or changes in the arrangement of pulleys due to shifting of machines may take place, it may be necessary to depend on empirical formulas for the design of shafting although the more fundamental method outlined above is to be preferred.

The following rules have been suggested for determining suitable diameters of mill shafting:

For shafts subjected to torque alone, *i.e.*, for power transmission over considerable distances between pulleys, and for short countershafts having bearings not more than 8 ft apart and pulleys close to bearings,

$d = \sqrt[3]{50\ \mathrm{hp}/N}$ for turned shafting $= \sqrt[3]{40\ \mathrm{hp}/N}$ for cold-rolled shafting, where hp = horsepower to be transmitted, N = rpm, and d = shaft diam, in.

When the shaft is a first receiving shaft, *i.e.*, a line shaft having bearings, 8 ft apart,

$d = \sqrt[3]{90\ \mathrm{hp}/N}$ for turned shafting $= \sqrt[3]{70\ \mathrm{hp}/N}$ for cold-rolled shafting.

When the shaft is a head shaft carrying the main driving pulley and distributing power to receiving or line shafts and is well supported by bearings,

$d = \sqrt[3]{125\ \mathrm{hp}/N}$ for turned shafting $= \sqrt[3]{100\ \mathrm{hp}/N}$ for cold-rolled shafting.

Table 50 is based on the formula $d = \sqrt[3]{90 \times \mathrm{hp}/N}$ and affords a rapid means of determining the shaft diameter for any desired transmission.

In line with the common practice of limiting the deflection of shafting to 0.01 in. per ft, the following rules for spacing hangers have been recommended. Let L = max distance in feet between bearings for continuous shafting: Then $L = \sqrt[3]{870d^2}$ for bare shafting or $\sqrt[3]{175d^2}$ for shafts carrying a fair proportion of pulleys placed near the bearings. It should be noted that these empirical rules may be considerably in error and that where speeds are moderate and loads are known the exact deflection of the shaft should be computed using the ordinary beam formulas as given on p. 462. For higher speeds, the following formula (Pinkney, *Machinery*, May, 1915) takes into account the effect of shaft speed in producing a centrifugal whirl:

$$L = K[1500/(N + 1500)]d^{2/3}.$$

For head shafts or so-called prime movers, also those shafts subjected to shocks and the bending action of pulleys, gears, etc., and which may be reversed under full load, $K = 5$. For the common type of lineshafts (except that part where the power is applied) and also for countershafts, with ample allowance for the bending action of pulleys, gears, etc., which are not reversed under full load, $K = 6.6$. For shafts and countershafts which are merely to transmit power without any bending action except that due to the weight of the bare shaft and with all pulleys close to the bearings, $K = 9.5$.

Standard Shaft Diameters and Lengths. In Table 51 are given standard diameters and lengths of shafting as approved tentatively by the A.S.A.

[1] These tolerances are negative and represent the maximum allowable variation below the exact nominal size. For instance, the maximum diameter of the $1\frac{15}{16}$ in. shaft is 1.938 in. and its minimum allowable diameter 1.935 in.

Engine Shafts. Engine shafts may be designed for strength by the more fundamental methods outlined on pp. 797, 798. Often, however, these shafts

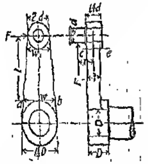

Fig. 61.—Overhung Crank.

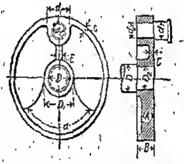

Fig. 52.—Crank Disk.

are designed from data representing good practice. Stationary steam-engine shafts were investigated by Trocien, who found the average proportions to be as follows:

For slow-speed and Corliss engines, $d = 7.2\sqrt[3]{hp/N} - 0.3$ in.

For high-speed center-crank engines, $d = 6.6\sqrt[3]{hp/N}$.

Universal Joints

Universal joints (Fig. 76) are couplings which are adapted to connecting *shafts fixed at an angle which is either constant or variable. The angular* velocity of the driving shaft being ω_1, the angular velocity ω of the driven shaft is varying during each revolution from a value $\omega_{max} = \omega_1/\cos\alpha$ to a value $\omega_{min} = \omega_1 \cos\alpha$, where α is the angle between the shafts. A double universal joint is often used to transmit motion between parallel offset shafts. If the pivots on the connecting jackshaft are set parallel to each other, the speed of the driven shaft is the same as that of the driving shaft.

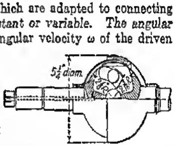

Fig. 77.—Weiss Universal Joint.

The **Weiss universal joint** (Fig. 77) has been used in automotive applications. This joint is designed to maintain equal speeds of the driving and driven shafts for any angle between the shafts. A number of steel balls *placed in intersecting races, cut in the two joint members, transmit* the motion. This joint permits axial movement of the shafts.

Clutches

Clutches are couplings providing for convenient disengaging of the coupled shafts during rotation.

Solid sleeve couplings are used for small shafts up to 2½ in. with moderate power and low speed. They consist of a cylindrical sleeve fitting closely on the coupled shafts which are held in place by set screws. The outside diameter is $3d$, the length is $4d$, where d is the diameter of the shafts.

Flexible Couplings

Flexible couplings allow for a slight occasional misalignment of the coupled shafts, both linear and angular. Following are shown typical flexible couplings. The ratings in horsepower per 100 rpm are given for smooth and steady loads. For uneven loads, the ratings must be ⅔, for shock loads ½ of the listed values.

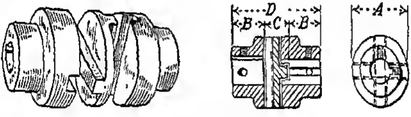

Fig. 67.—Double Slider Coupling.

Double slider couplings (Fig. 67) are used for heavy torques and moderate speed. The floating intermediate plate compensates the misalignment by a sliding movement. Dimensions, as made by Jones Foundry and Machine Co., Chicago, are given in Table 54.

For speeds greater than 100 rpm, the horsepower will be increased by the factor k.

Rpm	300	600	750	900	1200
k	2.5	3.5	3.75	4	4.25

Rubber bushing couplings (Fig. 68) consist of two steel disks, the driving disk having a number of rigid studs carrying a metal-lined rubber bushing. This projects into corresponding holes in the driven half. The dimensions and capacities of couplings

shaft axis and element of cone surface. f = coefficient of friction between the conical surfaces. N = rpm of shaft. W = width of cone surface, in. p = pressure normal to cone surface, lb per sq in.

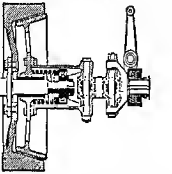

Fig. 80.—Cone Friction Clutch.

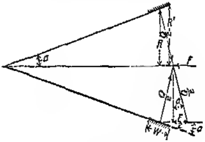

Fig. 81.

Then $T = QfR$; $F = Q(f\cos\alpha + \sin\alpha) = T(f\cos\alpha + \sin\alpha)/fR$.
Also $63{,}024 \times \text{h.p.}/N_1 = T = FfR/(f\cos\alpha + \sin\alpha)$
$\therefore F = 63{,}024 \times \text{hp}\,(f\cos\alpha + \sin\alpha)/NfR$
and $Q = 63{,}024 \times \text{hp}/NfR$. Also $Q = W \times 2\pi R \times p$.

Values of p are 7 to 8 lb per sq in. for leather faces and 40 to 50 lb for metal faces. In order that the clutch may not disengage of its own accord, tan α must be less than the coefficient of friction f. Accordingly, for leather or greasy metal, α would be 12 deg or less; or tan 12 deg = 0.213, which is less than f = 0.23. For free disengagement, wood or metal surfaces, $\alpha \gtreqless 20$ deg; leather-faced cone clutches with α = 18 to 20 deg need an operating device for disengagement (C. W. Hunt, *Trans. A.S.M.E.*, 30).

Ring friction clutches of a great variety of designs may be purchased on the market. The type manufactured by The Hill Clutch Co., Cleveland, Ohio, is illustrated in Fig. 82, dimensions and ratings being given in Table 65.

Cushioned plate couplings (Fig. 71) consist of two cast-steel flanged halves. Several rectangular slots are machined radially around their periphery to receive the cushioned torque transmitting steel plates. The plates are cushioned by four rectangular cushions, two in each flange, made of hydraulic packing. The plates and cushions are held in place by snap rings; each half is provided with a smooth steel cover, for safety. The dimensions and capacities for coupling of this type made by Westinghouse are given in Table 58.

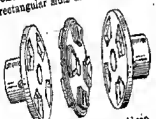

Fig. 70.—Grundy Flexible Coupling.

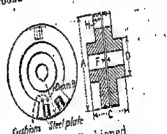

Fig. 71.—Cushioned Plate Coupling.

Flexible-band (belt-type) couplings (Fig. 72) have stud pins projecting from the driving and driven flanges. A tanned-leather belt is wound about the studs and acts as the intermediate driving connection. This coupling may be run in either direction and is very flexible. Dimensions and capacities of these couplings, as built by the Wood's Sons Co., Chambersburg, Pa., are given in Table 59.

Flexible steel member couplings transmit the torque from the driving to the driven element through a steel spring which allows for misalignment of the coupled

In Fig. 85, let C = leverage distance from fulcrum pin to line of action of P. Then, for clockwise rotation, $F(A + B) = RB - fRC$. For counterclockwise rotation, $F(A + B) = RB + fRC$.

In the case of clockwise rotation, it will be noted that C/B must be less than $1/f$, or the brake will be self-acting, *i.e.*, will bind.

In the arrangement shown in Fig. 86, for clockwise rotation, $F(A + B) = RB + fRC$ and for counterclockwise rotation, $F(A + B) = RB - fRC$.

In the latter case (for counterclockwise rotation), C/B must be less than $1/f$, or the brake will be self-acting, i.e., will bind.

Double blocks are used to eliminate bending of the shaft. Figure 88 illustrates one way in which such brakes may be rigged. The force relations are as follows:

Let F = load applied at end of lever, lb; R = reaction between wheel and *each* block, lb; P = tangential frictional resistance on each block surface, lb; f = coefficient of friction of materials in contact for a given condition of surface; r = drum radius, in.; T = torque on drum shaft, in-lb; other notations as in the figure. Then,

$$R = FA(c + d)/\cos(x/2)2Bc; \qquad P = Rf; \; T = 2Rfr.$$

The point o should be a floating pivot to permit adjustment as the blocks wear. Values of f are given in Table 64.

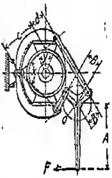

FIG. 88.

Should the face of the brake wheel and blocks be grooved, as shown in Fig. 87, $f/(\sin y + f \cos y)$ must be substituted for f in the foregoing equations, y being equal to half the angle included by the faces of the grooves and not less than 23 deg, to prevent binding; y may have any value up to 30 deg.

Band brakes are shown diagrammatically in Figs. 89, 90, and 91. The bands are usually of an asbestos fabric, sometimes reinforced with copper

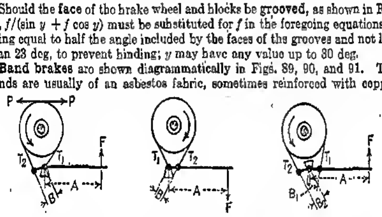

FIG. 89. FIG. 90. FIG. 91.

FIGS. 89–91.—Band Brakes.

wire and impregnated with asphalt. The force relations obtaining in their operations are as follows:

In Fig. 89, let F = force at end of brake handle; P = tangential force at rim of wheel; f = coefficient of friction of materials in contact; a = angle of wrap of band, deg; T_1 = total tension in band on tight side; T_2 = total tension in band on slack side. Then $T_1 - T_2 = P$ and $T_1/T_2 = 10^{0.0076fa} = 10^b$ where $b = 0.0076fa$. Also, $T_2 = P/(10^b - 1)$ and $T_1 = P \times 10^b/(10^b - 1)$. The values of $10^{0.0076fa}$ are given in Fig. 143 and Table 4, p. 242 (for a in radians).

For the arrangement shown in Fig. 89,

$$FA = T_2B = PB/(10^b - 1)$$

and

$$F = PB/A(10^b - 1)$$

For the construction illustrated in Fig. 90,

$$F = (PB/A)[10^b/(10^b - 1)]$$

For the differential brake shown in Fig. 91,

$$F = (P/A)[(B_2 - 10^bB_1)/(10^b - 1)]$$

Fast gear couplings (Fig. 75, Bartlett Hayward Co., Baltimore) have two spur gears on flanges mounted on each shaft and continually in mesh with corresponding internal gears of a floating sleeve. The clearance in the gear teeth allows for a slight linear and angular misalignment. Table 62 gives the dimensions and capacities of these couplings.

Let R = mean radius of cone surface, in.; Q = force normal to cone surface, lb; P = tangential force at cone surface, acting with the leverage R; F = axial force, lb; f = coefficient of friction between cone surfaces; a = angle between shaft axis and element of cone surface, deg; b = angle of pitch of worm on worm wheel, deg; f_1 = coefficient of friction of worm and wheel teeth; r = pitch radius of worm, in.; r_1 = pitch radius of ratchet wheel, in.; L = load on ratchet teeth, lb. Let $x = f \cos a + \sin a$, and $y = (\tan b - f_1)$; then Lr_1 = torque on worm shaft (in-lb) due to F, where F is the axial force due to load on drum = Fry approximately.

The resisting moment of the clutch is $PR = QfR = RFf/x$. To hold the load and prevent its lowering, the actuating torque Fry must be less than the reacting torque RFf/x. Accordingly, $Rf/x \geq ry$, or $R \geq ryx/f$. The angles a and b may be assumed 22 deg, f at 0.08, and f_1 at 0.10, depending on the lubrication, whence $x = 0.45$ and $y = 0.30$. Then for the above assumptions $R \geq 1.7r$. If $a = 30$ deg, $b = 35$ deg, then, for f and f_1 as before, $x = 0.57$, $y = 0.60$, and $R \geq 4.3r$.

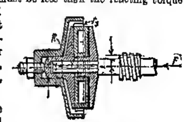

FIG. 94.—Disk Brake.

Disk brakes of the same general type of construction but using a flat face instead of a cone, are as shown in Fig. 94. There are two faces to be moved against friction.

The force relations are $Lr_1 \leq 2fFR = 2PR$, where $fF = P$. Also $R \geq ry/2f$.

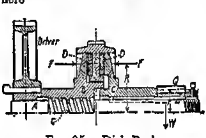

FIG. 95.—Disk Brake.

Frequently disk brakes are made as shown in Fig. 95. The pinion Q engages the gear in the drum (not shown). When the load is to be raised, power is applied through the gear and the connection between B and C is accomplished by the advancing of B along A and the clamping of the friction disks D and D and the ratchet wheel E. The reversal of the motor disconnects B and C. In lowering the load, only as much reversal of rotation of the gear is given as is needed to reduce the force in the friction disks so that the load may be lowered under control.

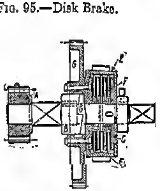

FIG. 96.—Multidisk Brake.

The force relations are as follows:

Let R = mean radius of friction plates, in.; f = coefficient of friction between plates; F = axial force along the screw = force in friction plates, lb; P = tangential force on friction plates at mean radius R, lb, $= fF$; W = load on pinion teeth, lb; r = radius of pinion pitch circle, in.; r_1 = radius of pitch circle of screw, in.; a = angle of screw thread, deg; f_1 = coefficient of friction in thread; $z = (\tan a + f_1)$.

Then the load in lowering causes a moment $Wr = fFR + Fr_1z$, approx. To sustain the load, $Wr \leq 2fFR$ and $fR \geq r_1z$.

Acceptable values of the several factors are: $a = 10$ deg; $f = 0.08$; $f_1 = 0.10$; $R = 9$ in. Substituting these in the last equation, $r_1 \leq 2.5$ in.+. Any radius of screw less than $2\frac{1}{2}$ in. consistent with strength will be satisfactory for the above conditions.

A multidisk brake is shown in Fig. 96. This type of construction results in an increase in the number of friction faces. The drum shaft is geared to the pinion A, while the motive power for driving comes through the gear G. In raising the load, direct connection is had between G, B, and A. In lower-

Square jaw clutches (Fig. 78) are used with shafts up to 4 in. diam for moderate speeds and power. Suitable proportions are: d = shaft diam in. and $k = d + 1$ in.; then $L = 2.65k$; $D = 2.1k$; $D_2 = 1.6k$; $D_3 = 1.5k$; $l = 1.25k$; $l_2 = 0.6k$; $x = y = 0.3k$.

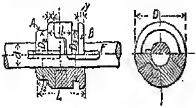

FIG. 78.—Jaw Coupling.

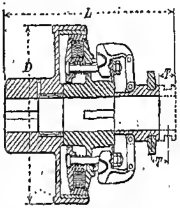

FIG. 79.—Plate Friction Clutch.

Plate Friction Clutches. A single disk clutch of this type is shown in Fig. 79 (Wood's Sons Co., Chambersburg, Pa.). Dimensions and capacities are given in Table 63. With two friction disks, the capacity of the coupling is doubled.

The force relation in plate friction clutches is as follows: Let R = mean radius of rubbing surface of rings, in.; T = torque transmitted, in.-lb; F = axial force, lb; f = coefficient of friction; n = number of rubbing surfaces;

Cone friction clutches (Fig. 80) are adaptable to connecting shafts whose loads are frequently thrown on and off. The force relations obtaining in the operation of this clutch are shown diagrammatically in Fig. 81 and may be formulated as follows:

Let R = mean radius of clutch cone surface, in. T = torque transmitted through the clutch, in.-lb. Q = total force normal to conical surface, lb. P = tangential force at cone surface acting with leverage R, lb. F = axial force required to engage clutch (lb) = force of the spring. a = angle between

counteracted by the face of a solenoid or a centrifugal thruster. Interruption of current automatically applies the spring-activated brake shoes. Figures 99 and 100 show electric brakes built by the General Electric Co.; the capacities and dimensions of the brakes are given in Table 67.

GEARING

Spur Gears

Definitions. The parts of spur gears are shown in Fig. 101. The **diametral pitch** P is the ratio of the number of teeth in the gear to the diameter of the pitch circle D_p measured in inches. The **circular pitch**

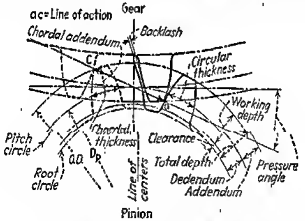

FIG. 101.—Gear Tooth Nomenclature.

p is the distance in inches on the circumference of the pitch circle between corresponding points of adjacent teeth. $P \cdot p = \pi$.

The **normal pitch** p_n is the distance along the line of action, between successive and corresponding involute tooth surfaces. $p_n = p \cos \phi$, where ϕ = pressure angle.

The **base circle diameter** D_b is the diameter of the base circle from which the involute is generated. $D_b = D_p \cos \phi$.

Magnetic clutches are being applied to the connecting of shafts even of large size. A clutch of this type manufactured by the Cutler-Hammer Mfg. Co. is shown in Fig. 83. Dimensions of C-H magnetic clutches and their capacities are given in Table 66.

BRAKES

Block brakes are shown diagrammatically in Figs. 84, 85, 86, and 87. They consist of a block or shoe of wood or cast-iron bearing upon an iron or steel

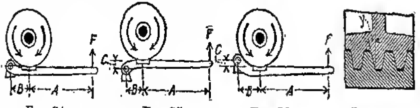

FIG. 84. FIG. 85. FIG. 86. FIG. 87.
FIGS. 84–87.—Block Brakes.

wheel. The force relations obtaining in the operation of these brakes may be formulated as follows:

In Fig. 84, let F = load applied at end of lever arm; A = distance from point of application of F to block center; B = distance from block center to center of fulcrum pin; R = reaction between wheel and block; f = coefficient of friction; P = tangential frictional resistance. Then, for rotation in either direction,

$$F(A + B) = RB, \quad R = P/f, \quad \text{and} \quad F = PB/f(A + B)$$

The shading in Figs. 102 to 107 shows the gear whose shaft has no motion.

Bevel Gears

Bevel gears may be used to connect two intersecting shafts in any given speed ratio. Occasionally bevel gears are used for non-intersecting shafts, in which case they are called skew bevel gears. A special type of skew bevel gearing developed by the Gleason Works and used widely in the automotive field is known as **hypoid gearing** (see *Jour. S.A.E.*, Vol. 18, No. 6). The involute tooth form is almost universally used for bevel gears.

Referring to Fig. 108, it is evident that the pitch surfaces of bevel gears must be frustrums of a pair of cones whose vertices are at the point of intersection of the axes.

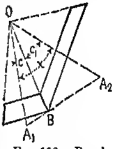

Fig. 108.—Bevel Gears.

There are three general types of bevel gears:

1. Right angle bevel gears (Fig. 109) in which the angle between intersecting shafts is 90 deg.
2. Acute angle bevel gears (Fig. 111) in which the angle between intersecting shafts is less than 90 deg.
3. Obtuse angle bevel gears (Fig. 112) in which the angle between intersecting shafts is greater than 90 deg.

Bevel gears having center angles, c and c_1, equal to 45 deg (Fig. 110) are called **miter gears**. The speeds of the shafts of bevel gears are determined by the following relation: $n/n_1 = \sin c_1/\sin c$, where $n(n_1)$ = rpm of pinion (gear) and $c(c_1)$ = center angle of pinion (gear) Fig. 109.

At the large end of the gear (Fig. 108), the tooth outlines will be approximately those generated on a pitch circle of radius BA_2. The formative number of teeth is the number of teeth which would be contained in a complete spur gear of pitch radius BA_2 (for the gear) and BA_1 (for the pinion). $T = N/\cos c$; $T_1 = N_1/\cos c_1$, where $T(T_1)$ = formative number of teeth in pinion (gear); $N(N_1)$ = actual number of teeth in pinion (gear). The formative number of teeth is used in selecting the proper cutter and also for obtaining the value of the Lewis factor when calculating the strength of the bevel gear.

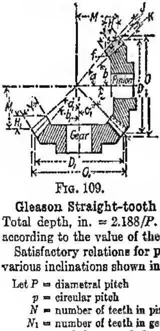

Fig. 109.

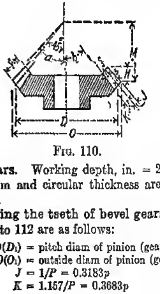

Fig. 110.

Gleason Straight-tooth Bevel Gears. Working depth, in. $= 2.000/P$. Total depth, in. $= 2.188/P$. Addendum and circular thickness are varied according to the value of the gear ratio.

Satisfactory relations for **proportioning** the teeth of bevel gears of the various inclinations shown in Figs. 109 to 112 are as follows:

Let P = diametral pitch
p = circular pitch
N = number of teeth in pinion
N_1 = number of teeth in gear
x = angle between shafts

$D(D_1)$ = pitch diam of pinion (gear)
$O(O_1)$ = outside diam of pinion (gear)
$J = 1/P = 0.3183p$
$K = 1.157/P = 0.3683p$

In this arrangement, the quantity $10^b \times B_2$ must always be less than B_1, or the band will grip the wheel and the brake, or part of the mechanism to which it is attached, will be ruptured.

It is usual in practice to have the leverage ratio A/B for block brakes about 5:1, and for hand brakes about 10:1. The bands are faced with maple blocks.

If f for wood on iron be taken at 0.3 and the angle of wrap for the band be 270 deg, *i.e.*, subtends $\frac{3}{4}$ of the circumference, then, $10^b = 4$ approx, and C/B be taken equal to $1/0.5 = 2$, the loads required for a given torque will be as follows for the cases just considered and for the leverage ratios stated above:

Block brake, Fig. 84	$F = 0.55P$
Block brake, Fig. 85 (clockwise rotation)	$F = 0.22P$
Block brake, Fig. 85 (counterclockwise rotation)	$F = 0.90P$
Block brake, Fig. 86 (clockwise rotation)	$F = 0.90P$
Block brake, Fig. 86 (counterclockwise rotation)	$F = 0.22P$
Band brake, Fig. 89	$F = 0.033P$
Band brake, Fig. 90	$F = 0.133P$
Band brake, Fig. 91	$F = 0.016P$

In the case of Fig. 91, the dimension B_2 must be greater than $B_1 \times 10^b$. Accordingly, B_1 is taken at $\frac{1}{4}$, A at 10, and, since $10^b = 4$, B_2 is taken at $1\frac{1}{2}$.

The principal function of a brake is to absorb energy. This energy appears at the surface of the brake as heat, which must be carried away at a sufficiently rapid rate to prevent burning of the wooden blocks. Suitable proportions may be arrived at as follows:

Let p = unit pressure on brake surface, lb per sq in. = R (reaction against block) /area of block; v = velocity of brake rim surface, fps = $2\pi rn/60$, where n = rpm of brake wheel. Then pvf = work absorbed per sq in. of brake surface per sec, and $pv \leqq 1{,}000$ for intermittent applications of load with comparatively long periods of rest and poor means for carrying away heat (wooden blocks); $pv \leqq 500$ for continuous application of load and poor means for carrying away heat (wooden blocks); $pv \leqq 1{,}400$ for continuous application of load with effective means for carrying away heat (oil bath).

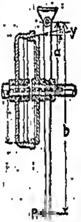

Fig. 92.—Cone Brake.

Cone brakes may be made to the form shown in Fig. 92. The force relations are as follows:

Let F = load applied at end of lever, lb; Q = normal pressure on cone surface, lb; P = tangential force on the rim of the brake, lb; r = mean radius of cone surface, in., and y = half angle of cone. Then $Q = F(b/a)/2(\sin y + f \cos y)$ and $P = fF(b/a)/(\sin y + f \cos y)$; $F = P(a/b)(\sin y + f \cos y)/f$. For $a = 1$, $b = 10$, $y = 15$ deg, and $f = 0.2$ for cast iron on cast iron, $F = 0.23P$, approx.

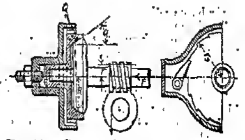

Fig. 93.—Cone Brake for Lowering Loads.

Such brakes are frequently used for lowering loads by the means shown in Fig. 93. The drum shaft is driven through the worm shaft by means of worm and wheel. In raising the load, the ratchet runs free. As the load tends to lower, the ratchet engages and the worm thrusts the cone surfaces together. Lowering of the load must be accomplished by the application of torque to the worm shaft. In the case of worms of small pitch, no brake is required, for the wheel cannot turn the worm. This brake is therefore adapted to worms of large pitch, and the reason for employing a large pitch is that a more efficient drive is obtained (see p. 827). The force relations are approximately as follows:

a 30-tooth worm wheel meshing with a single-threaded worm will have a velocity ratio of 1 to 30, *i.e.*, the worm must make 30 revolutions in order to revolve the worm wheel once. For a double-threaded worm, there will be 15 revolutions of the worm to one of the worm wheel, etc. High velocity ratios are thus obtained with relatively small wheels.

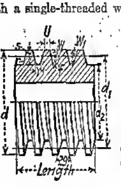

FIG. 114.

FIG. 115.—Hindley Worm Gear.

The following rules for **proportioning worm gears** are quoted from the "American Machinist Gear Book," by C. H. Logue, and refer to Figs. 113 and 114:

Let

- N = number of teeth in worm wheel
- N_1 = number of threads in worm
- p = circular pitch (dist c to c of teeth)
- L = lead (advance of worm in 1 rev)
- D_1 = pitch diam of worm wheel
- T = throat diam of worm wheel
- D = outside diam of worm wheel
- F = face of worm wheel
- a = distance from center line to point of tooth
- b = length of side
- d_1 = pitch diam of worm
- d = outside diam of worm
- d_2 = bottom diam of worm
- e = radius at throat of worm wheel
- c = angle of sides of face, deg
- B = center distance
- R = revs of worm per rev of wheel
- x = angle of teeth in wheel with axis (used in gashing)
- W = working depth
- W_1 = whole depth
- f = clearance
- t = thickness of tooth at pitch line
- t_n = normal thickness of tooth at pitch line
- p_n = normal circular pitch
- s = addendum
- U = width of worm thread at top
- Y = width of worm thread at bottom
- P = diametral pitch

Then

$$N = \pi D_1/p$$
$$T = 0.3183p(N + 2)$$
$$F = 2(0.5d + 0.17p)\sin c$$
$$= 0.5d + 0.17p \text{ approx}$$
$$a = F/2 - b\sin c$$
$$b = W_1 + 0.12p$$
$$d = d_1 + 2s$$
$$d_2 = d - 2W_1$$
$$e = \tfrac{1}{2}d_1 - s$$
$$c = 30 \text{ to } 35 \text{ deg}$$
$$\sin c = F/(d + 0.34p)$$
$$B = (D_1 + d_1)/2$$
$$D_1 = 0.3183Np$$
$$D = T + 2(s - e\cos c)$$
$$p = D_1/0.3183N$$
$$L = pN_1$$
$$N_1 = N/R$$
$$\tan x = L/\pi d_1$$
$$t_n = t\cos x, \text{ or}$$
$$t = t_n/\cos x$$
$$U = 0.335p = 1.0536/P$$
$$Y = 0.31p = 0.9744/P$$
$$p_n = p\cos x, \text{ or } p = p_n/\cos x$$

The formulas for the tooth parts of spur gears apply also to worm gears. N, D, and p are calculated the same as for spur gears.

T has the same value as the outside diameter of a spur gear of the same pitch and number of teeth.

F will usually be sufficiently accurate when calculated from the second formula.

d_1. The efficiency of a worm drive depends greatly on the helix angle x of the worm. When the lead is fixed, the angle is determined from $\tan x = L/\pi d_1$, and, in order to make it of a value that would ensure high efficiency, the diameter should be made small enough to provide a helix angle of about 30 deg. Little efficiency is gained in exceeding this angle (see Fig. 121). The preceding discussion assumes that the drive is to be speed reducing or that the worm drives. In the event of a speed increasing drive, where the gear drives, the designor should try to secure a helix angle between 45 deg and 60 deg.

ing, B moves relatively to G and forces the friction plates together, those plates fast to E being held stationary by the pawl on E. In the figure, there are three plates fast to E, one fast to G, and one fast to C.

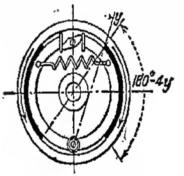

Fig. 97.—Internal Brake.

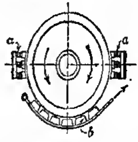

Fig. 98.—Eddy Current Brake.

In addition to the notation given in the previous case, let n = number of faces in sliding contact when the part C is moved relatively to part E which carries the ratchet. This condition obtains upon the load beginning to lower, and n_1 = number of *faces* in sliding contact when the parts G and C both move relatively to E. This obtains when full gripping of the plates takes place. The load in beginning to lower occasions the following force relation: $Wr = n_1fFR + Fr_2$. To sustain the load, it is necessary that $Wr \leqq n_1fFR$. Hence, to prevent the load from dropping, $r_2 \leqq fR(n_1 - n)$.

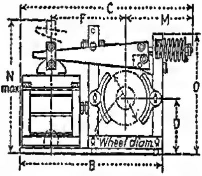

Fig. 99.—Solenoid-type Electric Brake.

Internal brakes are used extensively on most motor vehicles. The usual construction is shown in Fig. 97. The blocks are lined by a suitable friction material, usually asbestos woven with copper wire. In order to eliminate the possibility of binding, the angle y must be such that $\tan y \geqq f$. The angle a subtended by the brake is $a \leqq 180° - 4y$; $a \leqq 90°$ approx at $f = 0.4$ and $a \leqq 120°$ approx at $f = 0.2$.

Eddy current (brakes Fig. 98) are used with flywheels where quick braking is essential, and where large kinetic energy of the rotating masses precludes the use of block brakes due to excessive heating, as in reversible rolling mills. A number of poles a are electrically excited (north and south in turn) and create a magnetic flux which permeates the gap and the iron of the rim, causing eddy currents. The flywheel energy is converted through these currents into heat. The hand brake b may be used for quicker stopping when the speed of the wheel is considerably decreased, *i.e.* the eddy current brake is inefficient. Two brakes are provided to avoid bending forces on the shaft. (Siemens Schuckert Review, 1927, No. 5.)

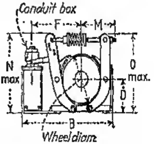

Fig. 100.—Thrustor-type Electric Brake.

Electric brakes are often used in cranes, bridges, turntables, and machine tools, where an automatic application of the brake is important as soon as power is cut off. The brake face is supplied by an adjustable spring which is

in common use are shown in Fig. 117. Correctly cut herringbone gears run much more smoothly than spur gears, and work silently and without vibration. They can also be run at higher speeds and higher velocity ratios. In the **Wuest system,** involute teeth with a 20 deg angle of obliquity are

employed, the pitch angle of the teeth being 23 deg. The face width is made equal to 6 × circular pitch p for gears with pinions of not less than 25 teeth, and $6p$ to $12p$ for high ratios with small pinions. For convenience in manufacture, the gears are grooved at the center of the face for a width equal to p and the two sets of teeth are stepped half the pitch apart. Pitch diameter $= N/P$ (for 20 teeth and over) $= (0.95N + 1)/P$ (for less than 20 teeth), where N = number of teeth and P = diametral pitch. Addendum $= 0.8/P$; dedendum $= 1/P$; working depth $= 1.6/P$.

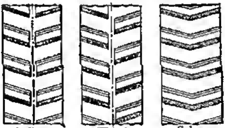

Fig. 117.—Herringbone Gears.

The gear teeth of De Laval herringbone gears for relatively high speeds are cut in steel forgings. For gears of relatively small diameters, the gear blanks and shaft are sometimes forged integral. On gears of relatively large size, a seamless rolled steel band is shrunk on a cast-iron center and the teeth are cut in this band. For pitch speeds above 3,000 fpm, a helical angle of approximately 45 deg is used in order that the maximum number of teeth may be engaged at the point of contact. The angle of obliquity is 14½ deg. *High speed helical gears have not less than 31 teeth in a pinion. Tooth* pressures in pounds per lineal inch of working face measured parallel to the shaft are limited to 60 times the diameter of the pinion in inches. The unsup-

The **gear ratio** m is the ratio of the number of teeth in the gear N_g to the number of teeth in the pinion N_p. $m = N_g/N_p$. The pinion is the wheel having the lesser number of teeth.

The **face** of a gear is the width of the tooth surface, measured parallel to the axis of the gear. The **center distance** is the distance between axes of mating gears.

Outlines and Proportions of Gear Teeth. The outlines of the teeth of gears in practice are almost always involute curves. The use of cycloidal and other curves is very rare. An involute curve (see p. 153) is generated by a point in a taut cord unwrapped from a base circle. One advantage of involute gearing is that uniform angular motion is transmitted, even though the center distance be changed slightly.

Tooth proportions for various systems adopted by the A.S.A. are given in Table 68.

Table 68. Tooth Proportions in Various Systems
(Dimensions in inches.)

	Full Depth or Composite 14½ deg.	Full Depth Involute 20 deg.	Stub Involute 20 deg.
Addendum	$1/P$	$1/P$	$0.8/P$
Minimum dedendum (incl. clearance)	$1.157/P$	$1.157/P$	$1/P$
Minimum clearance	$0.157/P$	$0.157/P$	$0.2/P$
Minimum total depth	$2.157/P$	$2.157/P$	$1.8/P$

Total depth is the radial distance from tip of tooth to root circle.

The speed ratios of spur gears are inversely proportional to their pitch diameters. The pitch diameters necessary for any given speed ratio and distance of shaft centers may be obtained in the following manner:

Let C = distance between shaft centers, in.; m = ratio of radius of larger to smaller gear. Then, diameter of smaller gear (D_s), in. $= 2C/(1 + m)$.

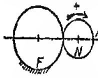

Fig. 102.

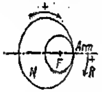

Fig. 103.

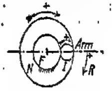

Fig. 104.

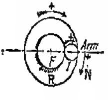

Fig. 105.

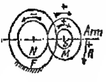

Fig. 106.

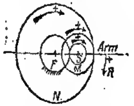

Fig. 107.

Figs. 102–107.—Epicyclic Gear Trains.

Diameter of larger gear (D_l), in. $= 2C/(1/m + 1)$. Accordingly, if $C = 24$ in. and $m = 5$, $D_l = 48/(6/5) = 40$ in., and $D_s = 48/6 = 8$ in.

For **epicyclic gear trains**, see p. 755.

The speed ratios (rpm of N ÷ rpm of R) for the more common gear trains are as follows:

Fig. 102. $1 + D_F/D_N$. Fig. 103. $1 - D_F/D_N$. Fig. 104. $1 + D_F/D_N$.
Fig. 105 (with internal gear driving). $D_R/(D_R + D_F)$.
Fig. 106. $1 - (D_F \times D_M)/(D_S \times D_N)$. Fig. 107. $1 + (D_F \times D_M)/(D_S \times D_N)$.

Herringbone Gears. Safe working pressure (lb) on the teeth of Wuest gears = $W = 0.4pFk$, where P = circular pitch, F = width of face (both in in.), and k has the following values determined by experiment:

	Velocity of pitch circle, fpm							
	200	400	800	1200	1600	2000	2400	2800
High-carbon-steel forgings	....	....	1550	1440	1320	1220	1120	1050
Steel castings	1300	1200	1100	1100	920	820	770	700
Phosphor bronze	1100	1040	920	830	750	690	630	590
Gun metal	960	880	750	650	580	530	500	460
Cast iron	760	690	590	500	450	410	390	370
Brass	600	520	440	400	360	330	310	300

Also W = hp × 33,000/V, where V = velocity of pitch circle, fpm.

Worm Gears. The allowable load (lb) on worm-gear teeth = $W = cbp$, where b = width of tooth and p = circular pitch—both in inches, and c = constant = 285 to 425 for cast-iron cut teeth = 455 to 711 for phosphor-bronze wheel and hardened steel worm such as are used for high speeds. These values are for the strength of the teeth only. For continuous running where heating and wear must be taken into consideration, c should have about the following values in the case of a phosphor-bronze wheel and a hardened and polished worm running in an oil bath:

NOTE: Table 70 from Marks, "Mechanical Engineers' Handbook," with modifications.

Then

$$N = DP = \pi D/p \qquad N_1 = D_1P = \pi D_1/p$$
$$D = N/P = 0.3183pN, \qquad D_1 = N_1/P = 0.3183pN_1$$
$$O = D + (2 \cos c/P) = D + 0.6366p \cos c\ [= D + (1.4142/P) = D + 0.45p \text{ for the miter gear in Fig. 110}]$$
$$O_1 = D_1 + (2 \cos c_1/P) = D_1 + 0.6366p \cos c_1$$
$$= D_1 + (2 \sin c/P) = D_1 + 0.6366p \sin c \text{ for Fig. 109}$$
$$\tan c = \cos(x - 90°)/[(N_1/N) - \sin(x - 90°)] \text{ for Fig. 112}$$
$$= \sin x/[(N_1/N) + \cos x] \text{ for Fig. 111; } = N/N_1 \text{ for Fig. 109}$$
$$c_1 = x - c$$
$$\tan s = 2 \sin c/N (= 1.4142/N \text{ for Fig. 110})$$
$$\tan f = 2.314 \sin c/N (= 1.6362/N \text{ for Fig. 110})$$
$$a = c + s (= 45° + s \text{ for Fig. 110}); \ a_1 = c_1 + s$$
$$b = c - f (= 45° - f \text{ for Fig. 110}); \ b_1 = c_1 - f$$
$$M = \tfrac{1}{2}O \cot a; \ M_1 = \tfrac{1}{2}O_1 \cot a_1$$
$$H = Y \cos a; \ H_1 = Y \cos a_1.$$

The number of teeth for which to select the cutter $= N/\cos c$ for pinions, and $N_1/\cos c_1$ for gears. For Fig. 110, this equals $1.414N$.

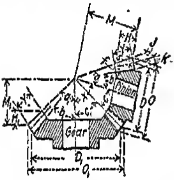

FIG. 111.

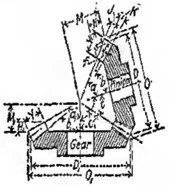

FIG. 112.

The pressure angles are as follows: for ratios having 14 or more teeth in pinion, 14½ deg; 13–13 to 13–24, 17½ deg; 13–25 and higher, 14½ deg; 12–12 and higher, 17½ deg; 11–11 to 11–14, 20 deg; 11–15 and higher, 17½ deg; 10–10 and higher, 20 deg.

Gleason Spiral Bevel Gears. Working depth, in. $= 1.700/P$. Total depth, in. $= 1.888/P$. The pressure angles are as follows: for ratios having 12 or more teeth in pinion, 14½ deg; 11–11 to 11–19, 17½ deg; 11–20 and higher, 14½ deg; 10–10 to 10–24, 17½ deg; 10–25 and higher, 14½ deg.

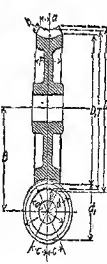

FIG. 113.

Worm Gears

Worm gearing is used for obtaining large speed reductions between non-intersecting shafts making an angle of 90 deg with each other. There are two classes of worm gearing in common use: straight worm gearing (Fig. 114) and **Hindley worm gearing** (Fig. 115). The latter gearing has a worm which is curved across the tops of the teeth and has a greater load-carrying capacity but lacks interchangeability and requires more careful machining and alignment.

With worm-and-wheel gearing, the **velocity ratio** is the ratio between the number of teeth on the gear and the number of threads on the worm. Thus,

In 1934, Schmitter published a design method based on this formula, with factors to take account of number of teeth in contact, face width, velocity effect, material, etc. This method has been developed with particular reference to the rating of helical and herringbone gear speed reducers (see "Manual of Gear Design," Section 3, Industrial Press, New York).

For application, the shear stress is multiplied by a service factor (Table 72).

Proportions of Gear Wheel Parts

The following represents Westinghouse-Nuttall practice in the design of industrial gearing.

The bores of gears and pinions are determined by the formula $b = \sqrt[3]{80h/n}$, where b = bore, in.; h = horsepower; n = rpm.

The hub diameter is made equal to $1.8b$, and the hub width equal to $1.25b$. For a gear with a face greater than $1.25b$, the width is made equal to the face.

The face of spur gears is made 3 or 4 times the circular pitch.

The minimum amount of metal permissible above the keyway of a pinion is determined by the following formula derived from application experience, $m = \sqrt{(t_p/5)}/P$, where m = minimum thickness of metal over keyway, in.; t_p = number of teeth in pinion; P = diametral pitch, in.

A six-arm gear is generally used whenever possible in the split and solid-type up to approximately 120 in. pitch diameter, and above this an eight-arm design is recommended. The four-arm design is generally used for split gears under 40 in. pitch diameter, with a narrow face and short hub to avoid special bolting. In calculating the arm sizes, the arm is considered as a cantilever beam with the load equally divided among the arms. First, the stalling load (or load at zero speed) is calculated according to the Lewis formula (p. 955). Then the section modulus is computed according to the flexure formula, $Z = Wr_p/Ns_o$, where Z = section modulus, in.^{3}; W = stalling load on teeth, lb; r_p = radius of pitch circle, in.; N = number of arms; s_o = working stress, lb per sq in.

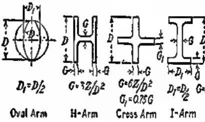

FIG. 120.—Gear Arm Sections.

The width of the arm in the plane of rotation is found by considering an elliptical cross section with a major axis of twice the length of the minor axis, $D = 2\sqrt[3]{Z/0.3927}$, where D = arm width at hub, in plane of rotation, in.; Z = section modulus, in.^{3}.

The width D found by the above method is used for arms having other cross sections (Fig. 120), the remaining dimensions of such cross sections being computed by the formulas given under the cross sections in Fig. 120.

The arms are made tapered ¼ in. per ft, with dimension D applying to the large end at the hub.

The rim thickness is proportioned according to the following formula: $J = \sqrt{(0.5t_g/N)}/P$, where J = thickness of rim inside of root diameter, in.; t_g = no. teeth in gear; N = number of arms; P = diametral pitch, in.

Phenolic Laminated Pinions. Certain special precautions should be taken in design of phenolic laminated pinions. The root diameter of the pinion should be such that the minimum distance from the edge of the keyway

c is generally from 30 deg to 35 deg. When the helix angle is 20 deg or over, c should not exceed 30 deg. When it is less than 20 deg, c may be taken as 35 deg.

L = circular pitch × number of threads in the worm; *e.g.*, a double-threaded worm of 1½ in. circular pitch has a lead of 3 in.

N_1. The number of threads in a worm of given velocity ratio = number of teeth in the wheel divided by the ratio; *e.g.*, for a wheel with 60 teeth and a velocity ratio of 30 : 1, number of threads = $N_1 = 60/30 = 2$.

W_1 should be proportioned from the normal pitch (p_n) rather than from the linear pitch (p), as is usually the case. It is wrong to take the depth from linear pitch even for single or double threads, and for quadruple and sextuple threads the error becomes so pronounced that it is likely to affect seriously the working of the gear.

t_n = thickness of tooth parallel with the axis of worm (= 0.5 × linear pitch) divided by the cosine of the helix angle x.

The length of the worm need be no greater than 3 times the circular pitch, as seldom are more than two teeth in contact at once. If the worm be made longer, however, it can be shifted lengthwise when worn, as it always wears away more rapidly than the wheel. It is common practice to make the length of worm = $6p$.

For strength of worm gears, see p. 824; for efficiency, pp. 240 and 827.

Helical Gears

Helical gears (commonly misnamed "spiral" gears) may be used to connect (1) parallel shafts, (2) shafts at right angles and not intersecting, and (3) shafts inclined at any angle to each other and not intersecting. Worm gears form a special case of (2). Figure 116 represents two helical gears connecting non-intersecting shafts inclined to each other in plan at an angle of c degrees. Gear A, of radius R, has teeth of a pitch angle equal to x deg, while the pitch angle of the teeth of gear B is equal to x_1 deg; the radius of gear B is R_1. Let n = rpm of A and n_1 = rpm of B; then the linear velocity of the pitch surface of $A = 2\pi Rn$, and the component of the velocity in the direction of the normal to the tooth profiles is $2\pi Rn \cos x$. Similarly, for gear B, the component of the velocity in the direction of the normal to the tooth profiles is $2\pi R_1 n_1 \cos x_1$. When helical gears are in mesh, however, the normals to the tooth profiles at the point of contact are coincident and the velocities in the direction of the normals are identical in value; hence $2\pi Rn \cos x = 2\pi R_1 n_1 \cos x_1$, or $n/n_1 = R_1 \cos x_1 / R \cos x$.

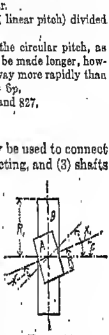

FIG. 116.

The problem of connecting a pair of shafts by helical gears for any velocity ratio admits of a number of solutions, since both the radii of the pitch surfaces and the angles of the teeth contribute to establishing the velocity ratio. The formulas given in Table 69 will be found of assistance in the computation of helical gears. The notation used in this table is as follows:

$N_1(N_2)$ = number of teeth in driver (follower)
$d_1(d_2)$ = pitch diam of driver (follower)
$p_1(p_2)$ = circular pitch of driver (follower)
p_n = normal circular pitch for both gears
P = normal diametral pitch for both gears
$D_1(D_2)$ = outside diam of driver (follower)
S_n = addendum of normal pitch
a = tooth pitch angle of follower
b = tooth pitch angle of driver
$L_1(L_2)$ = lead of driver (follower)
= lead of tooth helix
$r_1(r_2)$ = rpm of driver (follower)
c = angle between shafts in plan
C = center distance.

When helical gears are used to connect parallel shafts, the normal component of the tangential pressure on the teeth produces end thrust of the shafts. To remove this objection, such gears are made with right-handed helical teeth on one side of the face and left-handed on the other, and are then known as **herringbone gears**. The classes of herringbone gears

For **alloy steels for automobile transmission gears,** see S.A.E. specifications, p. 539.

The major non-metallic gear materials are phenolic laminated (Formica, Micarta, Textolite, etc.) and rawhide. Fiber and other materials are also used, but to a smaller extent. Non-metallic materials are used where quietness is of prime importance; usually one member of the mating pair is non-

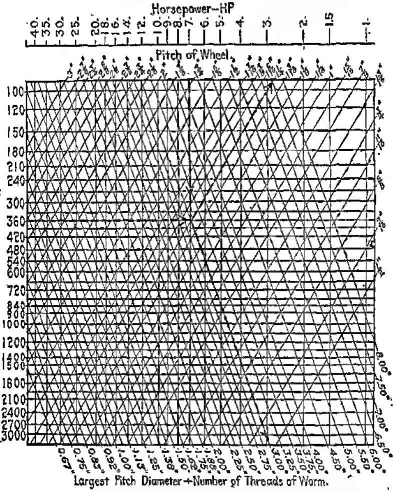

FIG. 122.—Diagram for Designing Worm Gearing of Maximum Efficiency.

metallic and the other metallic. Rawhide when made into a gear requires metallic side plates to provide adequate support; the phenolic laminated materials are self-supporting. Rawhide is softer and may under some conditions be applied for extreme quietness. The phenolic laminated materials are moistureproof and are resistant to chemical attack.

Table 78. Composition of Cast Iron for Gears

	Si	S	P	Mn	Total carbon
Large gears	1.00–1.50	0.08–0.10	0.30–0.50	0.80–1.00	Low
Medium gears	1.50–2.00	Under 0.09	0.40–0.60	0.70–0.90	
Small gears	2.00–2.50	Under 0.06	0.50–0.70	0.60–0.80	

ported width of the working face of a pinion measured from the inner ends of the supporting bearings is kept less than 2½ times the diameter of the pinion. Gear-case bearing supports are made rigid without any adjustment of the bearings; this construction is absolutely essential for the satisfactory operation of high-speed helical gears. If properly cut and supported, the life of a high-speed helical gear is found to be 25 to 30 years provided the tooth pressures are kept within proper limits and the gear is properly lubricated. An involute tooth is used with an addendum 0.8×3.1416 times the normal pitch.

For large herringbone gear sets, the Westinghouse Co. makes use of a **floating frame** which carries the pinion and allows adjustment due to various load distortions.

Beam Strength of Gear Teeth

Spur Gears. The Lewis formula, published in 1893 and still widely used, considers a gear tooth as a cantilever beam with a concentrated load applied at the tip along the line of action (Fig. 118). It assumes that the total load is applied to a single tooth. The formula is

$$W = FS_0yc/P$$

Fig. 118.—Load on Gear Tooth (Lewis Formula).

where W is the total working load, lb; F the active face width, in.; P the diametral pitch, in.; y the form factor which combines effective beam length and section modulus (see Table 70); and c a velocity factor. For ordinary metal gearing, $c = 600/(600 + V)$; for carefully cut or ground gearing $c = 1200/(1200 + V)$; and for laminated phenolic or rawhide gearing $c = 150/(200 + V) + 0.25$; where V = pitch line velocity, fpm. The working stress S_0 lb per sq in. should be as follows: for non-metallic laminated phenolic materials or rawhide, 6,000; for cast iron, 8,000; for bronze, 12,000; for cast-steel, untreated, 18,000; for cast-steel, heat-treated, 28,000; for forged steel, untreated, 20,000; for forged steel, heat-treated, 25,000 to 35,000.

Allowable torque and horsepower, as functions of the above working load, are expressed approximately by

$$T = Wr_p \qquad \text{hp} = WV/33{,}000$$

where r_p = pitch radius, in.;

Bevel Gears. The Lewis formula becomes

$$W_1 = FS_0ycQ/P$$

where W_1 = equivalent working load, lb (tangential component of total load acting at tip of large end of tooth, assuming one tooth carries total load); F = active face width, in., measured along pitch element; P = diametral pitch at large end; S_0 = working stress, lb per sq in.; y = form factor (Table 70 for standard bevel gears, using *formative* number of teeth; Table 71 for the Gleason system using the *actual* number of teeth); c = speed factor, same as for spur gears; and Q = taper factor $= 1 - f/l_1 + f^2/(3l_1^2)$ where l_1 = slant height of pitch cone, in. (OB, Fig. 108). Allowable torque and horsepower are found by

$$T = W_1r_1 \qquad \text{hp} = W_1V_1/33{,}000$$

where r_1 = pitch radius at large end, in., and V_1 = pitch line velocity at large end, fpm.

largest ones. Variations from the standard sizes may usually be obtained but at extra cost.

Table 75. Dimensions of Standard Cast-iron Pulleys (Single Arm)

Diameter, in.	Maximum bore, in.	Face widths, in.	Diameter, in.	Maximum bore, in.	Face widths, in.	Diameter, in.	Maximum bore, in.	Face widths, in.
3 to 5	$1\frac{7}{16}$	2 to 10	11	$2\frac{15}{16}$	2 to 12	18 to 24	$3\frac{15}{16}$	2 to 20
6	$2\frac{7}{16}$	2 to 10	12 to 14	$2\frac{15}{16}$	2 to 14	25 to 26	$4\frac{7}{16}$	2 to 20
7	$2\frac{7}{16}$	2 to 10	15	$2\frac{15}{16}$	2 to 16	27 to 48	$4\frac{7}{16}$	2 to 24
8	$2\frac{7}{16}$	2 to 12	16	$2\frac{15}{16}$	2 to 18	49 to 60	$4\frac{15}{16}$	6 to 24
9	$2\frac{7}{16}$	2 to 12	17	$3\frac{15}{16}$	2 to 18	61 to 72	$5\frac{15}{16}$	6 to 24
10	$2\frac{15}{16}$	2 to 12						

It should be noted that because of indeterminate shrinkage strains the calculation of stresses in the arms of cast-iron pulleys is, at best, very rough. *In general, such pulleys are not recommended for speeds over 5,000 fpm.* Where severe operating conditions, shocks, etc., are present, the use of an all-steel pulley is advisable. All-steel pulleys either of the solid or split type, consisting of wrought-steel arms cast into a semisteel hub, the arms being welded to a heavy plate steel rim, are made by Medart Co. The outer ends of the arms are bent to form rim lugs. By this means, shrinkage stresses are reduced and a much stronger pulley is obtained. Such pulleys may be purchased in standard sizes with diameters ranging from 24 to 192 in. and face widths from 6 to 50 in.

Wood split pulleys may be obtained from the manufacturer in diameters from 4 to 120 in. and face widths from 3 to 24 in. in standard sizes, with larger ones available on special order. Such pulleys, although much cheaper than the metal pulleys, should not be used in damp places, for high speeds, or where shock loads occur.

Stresses in Pulleys, Sheaves, and Flywheels—Proportions

Arms of pulleys, sheaves, and flywheels are subjected to stresses due to condition of founding, to details of construction (such as split or solid), and to conditions of service, which do not readily admit of analysis. For this reason, no accurate stress relations can be established, and the following formulas must be understood to be only approximately correct. It has been established experimentally by Benjamin (*Am. Mach.*, Sept. 22, 1898) that thin-rim pulleys do not distribute equal loads to the several pulleys arms. For these, it will be safe to assume the tangential force on the pulley rim as acting on half the number of arms. Pulleys with comparatively thick rims, such as engine band wheels, have all the arms taking the load. Furthermore, while the stress action in the arms is similar to that in a beam fixed at both ends, the amount of restraint at the rim depending on the rim's elasticity, it may, nevertheless, be assumed for purposes of design that cantilever action is predominant. The bending moment at the hub in arms of thin-rim pulleys will be $M = PL/\frac{1}{2}N$, where M = bending moment, in.-lb; P = tangential load on the rim, lb; L = length of the arm, in.; and N = number of arms. For thick-rim pulleys and flywheels, $M = PL/N$.

For arms of elliptical section having a width of 2 times the thickness, where E = **width of arm section** at the rim, in., and s_t = intensity of tensile stress, lb per sq in.,

Peripheral velocity of worm, fps... =	3.3	8.2	13.1	18	23
c =	426–570	356–426	285–340	213–256	142–170

Helical Gears. Use Lewis formula for spur gears, p. 823. Any error introduced by this method will be on the safe side.

Surface Strength of Gear Teeth

The general solution, by Hertz, of the stress distribution due to two elastic bodies in contact has been applied by Jandasek to gear design. Since contact stresses are quite localized, the special case of two cylinders in contact is applicable to the contact region of gear teeth. The basic Hertz equation for maximum compressive stress is

$$S_c = 0.583\sqrt{W\left(\frac{1}{R_1}+\frac{1}{R_2}\right)\Big/\left(\frac{1}{E_1}+\frac{1}{E_2}\right)}$$

where S_c is the maximum compressive stress; W the load per inch of face; E_1 and E_2 the moduli of elasticity; and R_1 and R_2 the radii of curvature at the contact point (Fig. 119).

The width of the contact area is

$$b = 2.185\sqrt{W\left(\frac{1}{E_1}+\frac{1}{E_2}\right)\Big/\left(\frac{1}{R_1}+\frac{1}{R_2}\right)}$$

Buckingham has developed a formula for spur gears which is also based on the Hertz maximum compressive stress (see "Manual of Gear Design," Section 2, Industrial Press, New York).

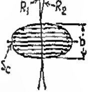

FIG. 119.—Pressure Distribution at Contact of Teeth.

In 1926, Timoshenko suggested that a more logical criterion would be the maximum shear stress.

$$S_s = 0.175\sqrt{W\left(\frac{1}{R_1}+\frac{1}{R_2}\right)\Big/\left(\frac{1}{E_1}+\frac{1}{E_2}\right)}$$

The maximum shear stress is approximately $3/10$ of the maximum compressive stress, so that qualitatively the methods are not essentially different. The maximum shear stress occurs at a depth equal to $0.393b$. For steel, the preceding equation becomes

$$S_s = 676\sqrt{W\left(\frac{1}{R_1}+\frac{1}{R_2}\right)}$$

Table 72. Service Factors for Shear Stress in Gear Teeth
(*Elec. Jour.*, Sept., 1937)

Character of load on driven machine	Turbine or electric motor drive			Multicylinder gas or steam engine			Single-cylinder gas engine		
	Intermittent, 3 hr per day	8–10 hr per day	24 hr per day	Intermittent, 3 hr per day	8–10 hr per day	24 hr per day	Intermittent, 3 hr per day	8–10 hr per day	24 hr per day
Uniform	0.8	1.0	1.25	1.0	1.25	1.5	1.25	1.5	1.75
Moderate shock	1.0	1.25	1.5	1.25	1.5	1.75	1.5	1.75	2.0
Heavy shock	1.5	1.75	2.0	1.75	2.0	2.25	2.0	2.25	2.5

joining arm. Then $s_t = 0.00034n^2R(w_1L_1 + wL/2)/Z$, where n = rpm of wheel; R = wheel radius, ft; and Z = modulus of rim section. The above equation gives the value of s_t for bending when the bolts are loose, which is the worst possible condition that may arise. On this basis of analysis, s_t should not be greater than 8,000. The stress due to bending in addition to the stress due to rim expansion as analyzed previously will be the probable maximum intensity of stress for which the rim should be checked for strength. The flange bolts, because of their position, do not materially relieve the bending action. In case a tie rod leads from the flange to the hub, it will be safe to consider it as an additional factor of safety. When the tie rod is kept tight, it very materially strengthens the rim.

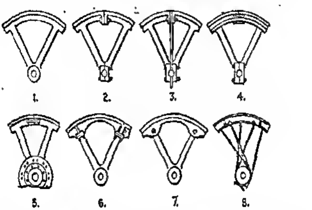

FIG. 128.—Types of Flywheel Construction (see Table 76).

A more accurate method for calculating maximum stresses due to centrifugal force in flywheels with arms cast integral with the rim is given by Timoshenko "Strength of Materials," Part II, 1930, p. 451. More exact equations for calculating stresses in the arms of flywheels and pulleys due to a combination of belt pull, centrifugal force, and changes in velocity are given by Heusinger, *Forschung Ing. Wes.*, 1938, p. 197. In both treatments, shrinkage stresses in the arms due to casting are neglected.

The relative strengths of different types of wheel construction are shown by the results of Benjamin's experiments on the bursting of flywheels (*Trans. A.S.M.E.*, 1899, 1902). The types of wheels experimented with and the speeds at which they burst are shown in Fig. 128 and Table 76.

Table 76. Test Data on the Flywheels of Fig. 128

Number.*	1	2	3	4	5	6	7	8
Number of arms	6	6	6	6	8	6	6	24
Rim speed at failure, fps = v	395	194	225	305	256	223	393	424
Comparative rim speeds at failure	100	49	57	77	65	56.5	100	107
Apparent rim tension at failure lb per sq in. = $v^2/10$	15,625	3,764	5,062	9,302	6,502	4,973	15,445	17,978
Efficiency† of construction	0.85	0.19	0.265	0.49	0.34	0.26	0.84	0.94

* Construction of flywheels: No. 1, solid wheel; No. 2, in halves, with flange joints; No. 3, in halves, with reinforced joints; No. 4, in halves, with link joints; No. 5, segmental, with link joints; No. 6, in halves, with pad joints; No. 7, solid rim, separate spider; No. 8, solid rim, with tangent spokes.

† Efficiency assuming tensile strength at 19,000 lb per sq in.

to the root circle shall be at least equal to the depth of tooth. The keyway compressive stress should not exceed 3,000 lb per sq in., which forms the basis of the formula:

$$LA = 84H/ND$$

where L is the length of keyway, in.; A the depth of key, in. (keyway in gear is approx ½ this value); H the horsepower; N the rpm; and D the diameter of shaft, in.

Taper keys which can be driven in place should ordinarily not be used for phenolic laminated pinions.

Efficiency of Gearing in Power Transmission

(See p. 240)

Spur and Bevel Gears. The efficiency of power transmission by the use of spur and bevel gears is very high. The loss of power for each set of spur gears in a train, where an oil bath is provided and the gears are generated by modern machinery, does not ordinarily exceed one-half of one percent. Where generated bevel gears are mounted under the same conditions and provided with antifriction thrust bearings, the efficiency per pair of gears should easily be 99 percent. The use of bevel gearing with plain thrust collars for power transmission is practically obsolete.

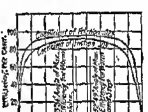

Fig. 121.—Efficiency of Worm Gearing.

The efficiency of **worm gearing,** when the friction of the thrust bearing is neglected, is $E = \tan \alpha\ (1 - f \tan \alpha)/(\tan \alpha + f)$ approx, where E = efficiency, α = angle of thread, and f = coefficient of friction. With values of $f = 0.025$ and 0.05, the variation of efficiency with thread angle is as shown in Fig. 121.

Self-locking worms are obtained when $f = \tan \alpha$. The efficiency resulting with such angles can never be as much as 50 percent. In practice, $\tan \alpha$ can be made greater than f and the gear will be self-locking because of the friction in other parts of the drive.

To find the pitch of worm-wheel teeth and the largest pitch diameter of worm **to transmit a given horsepower** at a given speed at maximum efficiency, the diagram shown in Fig. 122 may be employed (*Machinery*, May, 1912). To transmit 7 hp with a single thread worm at 360 rpm there is required, as shown by the diagram, a worm pitch diameter of 3 in. and a circular pitch of worm-wheel of 1¼ in. For cast-iron worm wheels and worms with unfinished teeth, the pitch should be 1⅓ times that obtained from the diagram.

The above remarks on efficiency of worm gearing apply to running conditions only. At the moment a worm drive is started from rest, the losses are from 2 to 3 times the above indicated running losses. Thus a single-thread worm drive showing by test a running efficiency of 70 percent showed a loss of over 50 percent at the moment of starting.

Materials for Gears

(See also p. 620 for phosphor bronze)

For cast-iron gears, the compositions given in Table 73 are used. For phosphor-bronze worm wheel with steel worm, a satisfactory composition is: Cu, 89.5 percent, Sn, 10 percent, P, 0.5 percent.

The value of r, the internal length of the link, is given by $r = L - 2d$, where L is the outside length of the link and d is the diameter of chain stock. These last quantities and the width of the link W are given in Table 80. In

Friction Gearing

Friction gearing of either the spur or bevel gear type may be used for the transmission of power. In either case, it is good practice for the driver to be of paper, leather, or pulp composition, and the driven wheel of metal, which may be iron, type metal, aluminum, etc. Goss (*Trans.* A.S.M.E., 29, 1907), reports as follows on the characteristics of friction drives:

The **safe working pressures** in pounds per square inch are as follows: straw fiber, 150, leather fiber, 240; tarred fiber, 240; sulphite fiber, 140; leather, 150. They are taken as 20 percent of the ultimate resistance of the material to crushing.

The safe working values of the **coefficient of friction** may be 60 percent of the values found from laboratory experiments. The frictional and power coefficients in Table 74 are calculated upon this basis.

Table 74. Frictional and Power Coefficients for Friction Gearing

Hp transmitted = $kwd\,N$

where w = width of face of driver, in.; d = diam of driver, in.; N = rpm

Tarred fiber....	Aluminum..	0.18	0.00035				

In the case of **bevel friction gears,** the horsepower may be had from the above values by taking for N a value which will correspond to the average velocity and radius of the pitch surface. In the case of **wedge-surface friction gears,** as shown in Figs. 123 and 124, the tangential force P for a given normal force Q pressing the wheels together is $P \leqq Qf/(\sin\alpha + f\cos\alpha)$, where f is the coefficient of friction. Generally, α = 10 to 15 deg. The radial depth of contact of the surfaces e (Fig. 123) should not exceed ½ in. The efficiency of friction drives, according to Ernst, may range from 88 to 90 percent. In **disk drives,** the distance between the face of the driver and the center of the driven wheel should not be less than 12 times the face width of the driver, otherwise the power capacity will be decreased due to slip.

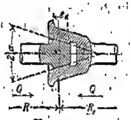

Fig. 123.

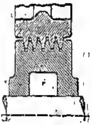

Fig. 124.

Wedge-surface Friction Gears.

PULLEYS, FLYWHEELS, SHEAVES, DRUMS

Cast-Iron pulleys are made in standard sizes, either solid, or with split hubs and rims, the single arm types being made in the standard sizes shown in Table 75 (data from Medart Co.). For multiple-arm pulleys, the standard diameters vary from 12 to 60 in., the face widths from 13 to 66 in., and the maximum bore sizes from $3\frac{7}{16}$ in. for the smallest pulleys to $6\frac{15}{16}$ in. for the

with fewer than 25 teeth, running at speeds above 500 or 600 rpm, should be heat-treated to give a tough wear-resistant surface testing between 35 and 45 on the Rockwell C hardness scale.

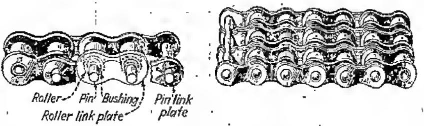

FIG. 137.—Roller Chain Construction.

If the speed ratio requires the larger sprocket to have as many as 128 teeth, or more than 8 times the number on the smaller sprocket, it is usually better, with few exceptions, to make the desired reduction in two or more steps. The American Standard tooth form allows roller chain to adjust itself to a larger pitch circle as the pitch of the chain elongates owing to natural wear in the pin-bushing joints. The greater the number of teeth, the sooner the chain will ride out too near the ends of the teeth.

[a] Not made in multiple strands.

$$E = \sqrt[3]{40PL/s_tN} \text{ (thin rim)} = \sqrt[3]{20PL/s_tN} \text{ (thick rim)}$$

For single-thickness belts, P may be taken as 50 B lb and for double-thickness belts $P = 75\ B$ lb, where B is the width of pulley face, in. Then $E = k \times \sqrt[3]{BL/s_tN}$, where k has the following values: for thin rim, single belt, 13; thin rim, double belt, 15; thick rim, single belt, 10; thick rim, double belt, 12. For cast iron of good quality, s_t due to bending may be taken at 1,500 to 2,000. The arm section at the rim may be made from ⅔ to ¾ the dimensions at the hub.

For high-speed pulleys and flywheels, it becomes necessary to check the arm for tension due to rim expansion. It will be safe to assume that each arm is in tension due to one-half the centrifugal force of that portion of the rim which it supports. That is, $T = As_t = Wv^2/2NgR$ (lb) where T = tension in arm, lb; N = number of arms; v = speed of rim, fps; R = radius of pulley, ft; A = area of arm section, sq in.; W = weight of pulley rim in lb and s_t = intensity of tensile stress in arm section, lb per sq in. Whence $s_t = WRn^2/5800NA$, where n = rpm of pulley.

Arms of flywheels having heavy rims may be subjected to severe stress action due to the inertia of the rim at sudden load changes. There being no means of predicting the probable maximum to which the inertia may rise, it will be safe to make the arms equal in strength to ¾ of the shaft strength in torsion. Accordingly, for elliptical arm sections,

$$N \times 0.5E^3s_t = ¾ \times 2s_sd^3, \qquad \text{or} \qquad E = 1.4d\sqrt[3]{s_s/s_tN}$$

For steel shafts with s_s = 8,000 and cast-iron arms with s_t = 1,500,

$$E = 2.4d/\sqrt[3]{N} = 1.3d \text{ (for 6 arms)} = 1.2d \text{ (for 8 arms)}$$

where $2E$ = width of elliptical arm section at hub, in. (thickness $= E$) and d = shaft diameter, in.

Rims of belted pulleys cast whole may have the following proportions (see Fig. 125):

$$t_2 = ¾h + 0.005D; \qquad t_1 = 2t_2 + C; \qquad w = ⅛B \text{ to } ¼B;$$

where h = belt thickness, $C = \frac{1}{24}\,w$, and B = belt width, all in inches.

Engine hand wheels, flywheels, and pulleys run at high speeds are subjected to the following stress actions in the rim:

FIG. 125. FIG. 126.
Rims for Belted Pulleys.

Considering the rim as a free ring (*i.e.*, without arm restraint) and made of cast iron or steel, $s_t = v^2/10$ (approx), where s_t = intensity of tensile stress, lb per sq in. and v = rim speed, fps. For beam action between the arms of a solid rim, $M = Pl/12$ (approx), where M = bending moment in rim, in.-lb; P = centrifugal force of that portion of rim between arms, lb, and l = length of rim between arms, in; from which $s_t = WR^2n^2/450N^2Z$, where W = weight of entire rim, lb; R = radius of wheel, ft; n = rpm of wheel; and Z = modulus of rim section, in.³. In case the rim section is of the forms shown in Fig. 126, care must be taken that the flanges do not reduce the section modulus from that of the rectangular section. **For split rims** fastened with bolts as shown in Fig. 127, the stress analysis is as follows:

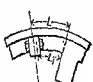

FIG. 127.

Let w = weight of rim portion L in. in length, lb; w_l = weight of lug, lb; L_l = lever arm of lug, in.; and s_t = intensity of tensile stress in rim section

Flywheels of the shrunk-link-joint type may be constructed as shown in Fig. 129 and to the dimensions given in Table 77. With cast-iron flywheels the bearing pressure on the link may be 20,000 lb per sq in. and the maximum shear on the head of the link 5,600 lb per sq in. The length of the link may be made $0.999D$, which gives an initial tension in the link of 30,000 lb per sq in.

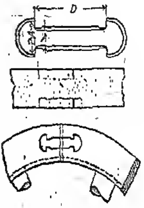

Fig. 129.—Shrunk-link Joint for Flywheels.

Large flywheels for high rim speeds and severe working conditions (as for rolling mill service) have recently been made from flat-rolled steel plates with holes bored for the shaft. A group of such plates may be welded together by circumferential welds to form a large flywheel. By this means, the welds do not carry direct centrifugal load, but serve merely to hold the parts in position. Flywheels up to 15 ft diam for rolling mill service have been constructed in this way.

Sheaves for Manila Rope Drives. The dimensions in inches of standard rope sheaves for manila rope drives (both for English and American systems) as used by Medart Co. are given in Table 78 where the letters refer to Figs. 130 and 131. For working sheaves or where arc of contact is under 90 deg, an angle of 45 deg is recommended; for tension and idler sheaves, 60 deg V sheaves are recommended.

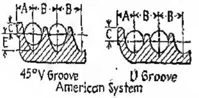

Fig. 130.

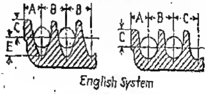

Fig. 131.

Figs. 130 and 131.—Dimensions of Grooves for Rope Drives.

Sheaves for ordinary link chains may be proportioned as shown in Figs. 132 and 133. The pitch diameter D is given by the equation

$$D^2 = (r/\sin a)^2 + (d/\cos a)^2$$

There should be at least 120 deg of wrap in the arc of contact on a power sprocket. For ratios of 3:1 or less, the wrap will be 120 deg or more for any center distance or number of teeth. To secure a wrap of 120 deg or more, for ratios greater than 3:1, the center distance must be not less than the difference between the pitch diameters of the two sprockets.

Sprocket Diameters. N = number of teeth; P = pitch of chain, in.; D = diameter of roller, in. The pitch of a standard roller chain is measured from the center of a pin to the center of an adjacent pin.

$$\text{Pitch diameter} = P/\sin\frac{180}{N}$$

$$\text{Bottom diameter} = \text{pitch diam} - D.$$

$$\text{Outside diameter} = P\left(0.6 + \cot\frac{180}{N}\right).$$

$$\text{Caliper diameter} = \left(\text{Pitch diam} \times \cos\frac{90}{N}\right) - D.$$

The exact bottom diameter cannot be measured for an odd number of teeth, but it can be checked by measuring the distance (caliper diameter) between bottoms of two tooth spaces nearest opposite to each other. Bottom and caliper diameters must not be oversize—all tolerance must be negative. A.S.A. negative tolerance $= 0.003 + (0.001 \times P\sqrt{N})$ in.

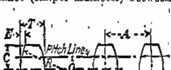

FIG. 139.—Sprocket Tooth Sections.

Design of Sprocket Teeth for Roller Chains. The section profile for the teeth of roller chain sprockets, recommended by the A.S.A., has the proportions shown in Fig. 139. Let P = chain pitch; W = chain width (length of roller); n = number of strands of multiple chain; M = over-all width of tooth profile section; H = nominal thickness of link plate, all in inches. Referring to Fig. 152, $T = 0.93W - 0.006$, for single strand chain; $= 0.90W - 0.006$, for double- and triple-strand chains; $= 0.88W - 0.006$, for quadruple or quintuple strand chains; and $= 0.86W - 0.006$, for sextuple-strand chain and over. $C = 0.5P$. $E = \frac{1}{8}P$. $R(\text{min}) = 1.063P$. $Q = 0.5P$. $A = W + 4.15H + 0.003$. $M = A(n - 1) + T$. Tolerance on sprocket thickness $= \pm(0.02W + 0.002)$.

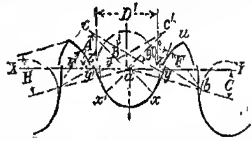

FIG. 140.—Laying Out a Standard Sprocket Tooth.

One of the most important requirements of a sprocket for roller chain is that the tooth space, or roller seat, should not be undersize. The size and shape of new straddle cutters, space cutters, or hobs should be checked carefully by cutting and testing a sample sprocket.

The method of laying out a standard sprocket tooth for roller chains is illustrated by Fig. 140. This form of tooth is recommended by the A.S.A. and is designed for maximum efficiency throughout the life of the drive. Because of the large pressure angle, the tendency of the teeth to wear hook-

CHAIN DRIVES

Roller Chain Drives. The advantages of finished steel roller chains are high efficiency (around 98 to 90 percent), no slippage, no initial tension required, chains may travel in either direction. The basic construction of roller chain is shown in Fig. 137.

The shorter the pitch, the higher the permissible operating speed of roller chain. Horsepower capacity in excess of that provided by a single chain may be had by the use of multiple chains which are essentially parallel single chains assembled on pins common to all strands. Because of its lightness in relation to tensile strength, the effect of centrifugal pull does not need to be considered; even at the unusual speed of 6,000 fpm, this pull is only 3 percent of the ultimate tensile strength.

Sprocket wheels with fewer than 16 teeth may be used for relatively slow speeds, but 18 to 24 teeth are desirable for high speed service. Sprockets

Having determined the proper pitch, the sprockets are next selected. On small motor drives, 17 to 21 teeth on the driver sprocket is good practice. For large speed ratios and a minimum number of teeth in the pinion, it is desirable to avoid extremely large driven sprockets; 127 teeth is a good limit, and less than 100 is preferred. Where the speed ratio is small, it is desirable to get at least 33 teeth in the driven wheel. It is usually well to select sprockets that will give a chain speed of 1,200 to 1,600 fpm. If in the design this figure is exceeded, this speed may be lowered by the use of smaller sprockets and smaller pitch. An odd number of teeth in both sprockets is desirable unless an exact ratio requires an even number. Although higher speeds than indicated in the table may often be used, it is best that such designs be submitted to the manufacturer for approval.

To find the required chain width, the total chain pull F is divided by the normal tension per inch as given in Table 84. Where the load is not uniform, the horsepower assumed in figuring the drive should be increased by multiplying the rated horsepower of the motor or prime mover used, by a factor as follows:

For electric motor (oil or gas engine) driver the factor with uniform load as in a line shaft, centrifugal pump exciter or most machine tools is 1 (1.25); with uneven or pulsating load as in a duplex pump, compressor with balance wheel, beaters, stokers, etc., 1.25 (1.5); with severe shock or reversing load as in a ball or tube mill, heavy rolling mills, drill rigs, crushers, etc., 1.5 (2). Where the drive is used 24 hr a day, an additional 25 percent should be added to the horsepower rating used in the computations. These ratings are based on chains in protecting cases with adequate lubrication.

2 1/2	69,600	60,300	49,200	34,800

The safe loads specified in the table are for each single chain; when used in any other multiple, the load may be increased proportionately. Stub hooks should be used for lifting apparatus which is provided with holes for that purpose.

Annealing and Care of Chains. In service, because of overloading or the peening or hammering action of the links on each other, chains tend to become brittle so that sudden failure may occur. To remove this condition, annealing of the chain at intervals is necessary. The following notes on annealing are published by the National Safety Council:

In cases where failure of a chain may result in loss of life or property, it is recommended that, where possible, the repair and annealing of such chains be entrusted to a company making a business of this work and having the necessary experience, equipment, and technical supervision to do it correctly. Such chains should be annealed as often as *careful inspection (to determine if a work-hardened condition exists, or if the chain has been overloaded)* shows this to be necessary. The annealing of wrought-iron chains should be carried out in a furnace provided with accurate temperature measurement and control, at 1350 to 1375 F for the following lengths of time: ¼ to ½ in. chain, ½ hr; ⅝ to 1 in. chain, ¾ hr; 1 to 1⅜ in. chain, 1 hr; over 1⅜ in., 2 hr. Cooling in air may follow the anneal. For steel chain, the corresponding annealing temperatures are 1600 to 1650 F. It is important that uniform temperature be obtained during annealing in all parts of the chain.

Table 88. Dimensions of Circular Rings Used at Ends of Sling Chains

3/4	1 3/8 × 6	1 3/4 × 7			

[a] First figu[illegible]r, second figure to inside ring diameter.

Idler sprockets may be used on either side of the standard roller chain, to take up slack, to guide the chain around obstructions, to change the direction of rotation of a driven shaft, or to provide more wrap on another sprocket. Idlers should not run faster than the speeds recommended as maximum for other sprockets with the same number of teeth. It is desirable that idlers have at least two teeth in mesh with the chain, and it is advisable, though not necessary, to have an idler contact the idle span of chain.

Horsepower ratings are based upon the number of teeth and the rotative speed of the smaller sprocket, either driver or follower. The pin-bushing bearing area, as it affects the allowable working load, is the important factor for medium and higher speeds. For extremely slow speeds, the chain selection may be based upon the ultimate tensile strength of the chain. For chain speeds of 25 fpm and less, the chain pull should be not more than 1/5 of the ultimate tensile strength; for 50 fpm, 1/6; for 100 fpm, 1/7; for 150 fpm, 1/8; for 200 fpm, 1/9; and for 250 fpm, 1/10 of the ultimate tensile strength.

Ratings for **multiple strand chains** are proportional to the number of strands. The recommended numbers of strands for multiple chains are 2, 3, 4, 6, 8, 10, 12, 16, 20, and 24, with the maximum over-all width in any case limited to 24 in.

FIG. 138

Chain Length Calculations. Referring to Fig. 138, L = length of chain, in.; P = pitch of chain, in.; R and r = pitch radii of large and small sprockets, respectively, in.; D = center distance, in.; A = tangent length, in.; a = angle between tangent and center line; N and n = number of teeth on larger and smaller sprockets, respectively; $(180 + 2a)$ and $(180 - 2a)$ = angles of contact on larger and smaller sprockets, respectively, deg.

$a = \sin^{-1}[(R - r)/D]$. $A = D \cos a$.

$$L = NP(180 + 2a)/360 + nP(180 - 2a)/360 + 2D \cos a$$

If L_p = length of chain in pitches, and D_p = center distance in pitches,

$$L_p = (N + n)/2 + a(N - n)/180 + 2D_p \cos a$$

Avoiding the use of trigonometrical tables,

$$L_p = 2C + (N + n)/2 + K(N - n)^2/C$$

where C is the center distance in pitches and K is a variable depending upon the value of $(N - n)/C$. Values of K are as follows:

$(N - n)/C$	0.1	1.0	2.0	3.0	4.0	5.0	6.0
K	0.02533	0.02538	0.02555	0.02584	0.02631	0.02704	0.02828

Formulas for chain length on multisprocket drives are cumbersome except when all sprockets are the same size and on the same side of the chain. For this condition, the chain length in pitches is equal to the sum of the consecutive center distances in pitches plus the number of teeth on one sprocket.

Actual chain lengths should be in even numbers of pitches. When necessary, an odd number of pitches may be secured by the use of an offset link, but such links should be avoided if possible. An offset link is one pitch; half roller link at one end and half pin link at the other end. If center distances are to be non-adjustable, they should be selected to give an initial snug fit for an even number of pitches of chain. For the average application, a center distance equal to 40 ± 10 pitches of chain represents good practice.

Steam-engine cylinders may have walls of the thickness, t(in.) = $(PD/2000) + 0.3$ in. The thickness thus obtained allows for reboring. For jacketed cylinders, the liner, when of cast iron, may be of the thickness $t_0 = [PD/(5125 + 10P)] + 0.4$ in.

Cylinders for hydraulic presses are usually designed with high working stresses used to reduce the weight of the cylinders:

Steel or cast-steel cylinders	15,000 to 30,000 lb per sq in.
Phosphor bronze	7,000 to 12,500 lb per sq in.
Cast iron, bronze	4,500 to 11,000 lb per sq in.

Cylinder flanges should not be thicker than 1.2t to 1.25t. Heavier flanges cause severe cooling strains which materially weaken the casting.

Cylinder heads when flat may be proportioned as flat plates supported at the edges. $t_1 = 0.45D\sqrt{5P/6f}$, where t_1 = thickness of plate, in., and f = allowable stress, lb per sq in. = 3,000 for cast iron and 8,000 for cast steel. When heads are **dished and ribbed**, the same formula may be used for determining the maximum limit of dimension and the actual thickness made 20 to 40 percent less, depending on the ribbing.

Flat cover plates may be designed as rectangular plates supported at the edges (see p. 475). The thickness of the plate is $t_2 = ka\sqrt{P/f}$, where a = the shorter side of the plate, in.; b = the longer side of the plate, in.; f = 3,000 for cast iron, 9,000 for cast steel; k depends on the ratio b/a and is as follows:

b/a =	1.0	1.2	1.4	1.6	1.8	2.0	3.0	4.0
k =	0.536	0.613	0.672	0.719	0.754	0.780	0.844	0.860

Large covers are usually dished and ribbed for added strength; the same values of k may be used for determining the maximum value of t_2 and the actual thickness made less, depending on the ribbing.

Stud bolts for holding down cylinder heads and steam-chest covers should never be less than ⅝ in. and preferably ¾ in. diam to prevent their being twisted off in tightening. The intensity of stress based on steam-pressure load should be limited to 6,000 lb per sq in., and the spacing should not be greater than 6½ in. or less than 3½ times the diameter of the bolt. If higher stress is necessary, special steel must be used. Stud holes should be tapped to a depth equal to 1½ times the diameter of stud, but never allowed to enter a steam space. The strength of the bolts should be much less than the strength of the frame or cylinder with load application along the center line of the engine. This will ensure the safety of the more expensive castings in case of unusual loading such as may be caused by water in the cylinder.

Pistons and Piston Rods

Small pistons may be made to the form and dimensions given in Fig. 143 and Table 90.

Larger pistons of this type are often reinforced by radial internal ribs. Proper holes, adequately bossed, must be provided for holding the cores in place and for removing them after casting. Ribs are not advisable for very high temperatures, superheated steam, or gas engines, causing excessive thermal stresses.

Disk pistons (Fig. 144) are often used. The thickness h of the disk, in., is $h = \sqrt{(k_1D^2 - k_2D_1^2)P/f}$; P = internal gage pressure lb per sq in.; f = the allowable stress lb per sq in.; k_1 and k_2 depend on the ratio d_1/D_1 and are as follows:

shaped is reduced, while the chain rides higher on the teeth as it elongates, thus accommodating itself to a larger pitch circle.

In Fig. 153, let P = pitch; D = nominal roller diameter, in.; N = number of teeth; $D' = 1.005D + 0.003$; $A = 35 + 60/N$ deg; $B = 18 - 56/N$, deg; $C = 180/N$ deg.

In laying out the tooth, first draw line XY. Locate point a, and with that as a center and radius ax equal to $1/2D'$, draw a circular arc for the "seating curve" xx'.

Draw line xac making angle A with line XY, and locate point c so that $ac = 0.8D$. Draw line cy making angle B with line cx. With center at c and radius cx, draw arc xy for the "working curve."

Draw line yz perpendicular to line cy. Draw line ab making angle C with line XY, and locate point b so that $ab = 1.24D$. Draw line bz parallel to line yc. With b as center and radius bz, draw the "topping curve," arc zu tangent to line zy.

A similar construction for the other half will complete the tooth outline.

Outside diameter of sprocket when tooth is pointed $= P \cot (180/N) + 2H$.

The recommended value for H is $0.3P$; and when this value is chosen, the outside diameter of the sprocket will be $P[0.6 + \cot (180/N)]$.

Silent Chains. Silent chain drives are widely used in various applications including front-end drives in automobile engines and in connecting high-speed electric motors to their loads. The advantages of silent chains in addition to their quietness in operation are high efficiency, suitability for high speeds, positive drive without slippage, ability to run on short or long centers, and the elasticity of their connection to the load.

FIG. 141.—Morse Silent Chain.

Morse Silent Chain. *The principal feature of* construction of the Morse silent chain is the rocker joint as shown in Fig. 141.

The procedure in the design of Morse silent chains is as follows: The pitch is selected first, the normal rpm of the high-speed shaft for each pitch being indicated in Table 84. In most drives, the largest pitch consistent with the maximum rpm as indicated in the table will be the most economical.

Table 84. Data on Design of Morse Silent-chain Drives

Pitch, in.	No. of pitches per ft	Normal rpm	Normal tension, 1 in. wide, lb	Min no. of teeth, driver	Desirable no. of teeth, driver	Min no. of teeth, driven
3/16	64	5,000	30	13	13-17	21
3/8	32	3,600	75	13	15-17	21
1/2	24	2,400	100	13	15-17	21
5/8	19.2	1,800	125	13	17-21	21
3/4	16	1,400	150	13	17-21	21
0.9	13.33	1,100	185	15	17-23	25
1	12	1,000	205	15	17-23	25
1.2	10	800	250	15	17-23	25
1¼	9.6	750	265	15	17-23	25
1½	8	600	335	17	17-27	25
2	6	400	600	17	17-31	27
3	4	250	935	17	19-31	27

When extreme quietness is desirable, it is recommended to use two pitches smaller than that indicated for the rpm given in the table.

the pressure p against the wall is $D = 2.4fA^2/EB$ or $2.4fA^2/EF$, where E is the modulus of elasticity of the ring material. The ring is preferably in segments for large engines, each segment being pressed against the cylinder walls by a spring.

Piston rods are subjected mainly to compressive stresses and may be designed as round free-ended columns, for which Euler's formula reduces to $P = 0.485Ed^4/sl^2$, in which P = total load, lb; E = modulus of elasticity ($= 30{,}000{,}000$ for mild steel); d = diam of rod, in.; l = length of rod, in. [For hollow piston rods, substitute $(d_2^4 - d_1^4)$ for d^4 in formula, d_2 and d_1 being, respectively, the outer and inner diameters.] The factor of safety s has the following values: For vertical engines $s = 8$ to 11 for load fluctuating between P and 0; $s = 15$ to 22 for load fluctuating between $+P$ and $-P$. In horizontal engines, the rods are also subjected to bending stress due to the combined weight of the piston and rod. In small engines with light pistons, the formula for vertical engines may be used with $s = 11$ to 22. In large engines with heavy pistons and rods running through glands in both heads (as in tandem steam and gas engines), the rod must be of such stiffness that it will not deflect at mid-length between its points of support more than 0.08 in. In this case, the piston diameter must be 0.12 to 0.16 in. less than that of the bore. Deflection in inches $= l^3(W_1 + 0.625W_2)/48EI$, where l = length between supported points, in.; W_1 and W_2 = weights of piston and rod, respectively, lb; I = moment of inertia of rod section $= \pi d^4/64$. Most reliable values of d may be found by the use of Ritter's long-column formula. This reduces to the following form for mild-steel rods:

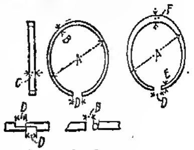

FIG. 146. FIG. 147.
Piston Rings.

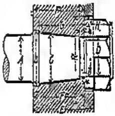

FIG. 148.—Piston-rod Ends.

$$d^2 = P(1 + \sqrt{1 + fl^2/190P})/1.57f$$

where f = allowable working stress, usually 5,000 lb per sq in., l = rod length, in., P = load on rod, lb.

Table 92. Typical Dimensions for Ends of Piston Rods
(All dimensions in inches. Letters refer to Fig. 148)

A	*B*	*C*	*D*	*E*	*F*	*G*	*H*	*R*
2¾	3¼	3	2½	4½	3¾	3⅛	2⅜	4¾
3	3½	3¼	2¾	4½	3¾	3⅛	2⅜	5¼
3¼	3¾	3½	3	5½	4¼	4⅛	2⅜	5¾
3½	4	3¾	3¼	5½	4½	3⅞	2⅞	6
3¾	4¼	4	3½	6½	5½	4⅞	2⅞	6½
4	4½	4¼	3¾	6½	5½	4⅞	2⅞	6⅞
4¼	4¾	4½	4	7	6	5⅜	3⅜	7¼
4½	5	4¾	4¼	7	6	5⅜	3⅜	7¾

To check for stress in an existing design, the formula is more conveniently written as: $f = P[1 + (16SL^2/\pi^2Ed^2)]/A$, where A = area of rod section, sq

For calculating silent chain lengths, the procedure for roller chain drives (p. 992) may be used.

CRANE CHAINS AND HOOKS

Crane Chains. For applications where failure is dangerous to life or property, chains made from a high grade of wrought iron are widely used. Because of its extreme ductility, wrought iron has a large shock-absorbing capacity, and chains made of this material will stretch considerably under an overload, unless they have been overstrained or the links embrittled. Wrought iron has the additional advantage that it is easily welded. Welded chains made of nickel steel (S.A.E. 2320) are also coming into use where exacting requirements must be met.

Table 86. Proof and Break Test Loads of Crane and Proof Coil Chain

1 3/4	80,800	......	161,600	......	48,450	
1 7/8	92,750	......	185,500	......	55,300	
2	105,500	......	211,100	......	63,300	

Nominal weights and dimensions for crane chains of wrought iron or steel as given in A.S.T.M. specification A-56-30 are given in Table 85; proof, break test, and safe working loads taken from the same specification are given in Table 86. The proof coil chain should be used only where life or property is not endangered by a chain failure and where corrosion is not a factor. **Proof coil** is made of steel—generally open-hearth—and is used for railroad cars and construction and forestry work.

The safe loads as recommended by Hantman (*Maintenance Engineering*, Oct., 1932) and used by Westinghouse Electric & Mfg. Co. for wrought-iron sling chains, used at various angles, are given in Table 87. These loads are somewhat lower than those indicated in Table 86.

The American Chain and Cable Co. recommends that chains used on the sheaves to operate cranes have straight-sided links (so as to operate properly in the sheaves), and chains used on slings should have oval-shaped links. Under overload, the oval-shaped links will tend to straighten out, thus giving visual warning that the chain is too light for the load.

Pin bushings are proportioned to have a maximum bearing pressure 1,000 to 1,200 lb per sq in. for steam engines, up to 2,500 lb per sq in. in oil or gas engines. In small connecting rods, this pressure is 300 to 700 lb per sq in., depending on the required rate of wear. The ratio of length to diameter of the bushing is 1.2 to 1.5.

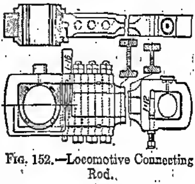

FIG. 152.—Locomotive Connecting Rod.

Shanks for connecting rods may be designed as long columns with round ends, using Ritter's formula (see p. 848), $d^2 = CP[1 + \sqrt{1 + (l^2kf/KCP)}]/kf$, where P = load on rod, lb; f = maximum allowable stress, lb per sq in.; l = length of rod, in. For rods of **circular cross section**, d = rod diam, in., C = 1.00, k = 1.57, and K = 300. For **rods of rectangular cross section** having height of section equal to 2.7 times the thickness, d = height of rod section, in.; C = 1.35, k = 1, and K = 420. These constants are for rods of mild steel having an elastic limit of 30,000 lb per sq in. and a modulus of elasticity in tension of 30,000,000 lb per sq in. In high-speed steam-engine practice, f may be 4,000. In slow-speed steam engines, gas engines and pumps, f may be 5,000 to 5,500. In general, the **working stress** for connecting rods should be ⅙ to ⅛ the stress at the elastic limit of the material, when designing for long-column action. Rods for high-speed engines having important inertia stresses should be designed with a factor of ⅙. The sum of the stresses due to long-column action and to inertia (whipping action) should not exceed ½ the stress at the elastic limit of the material.

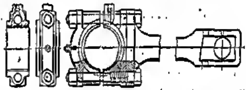

FIG. 153.—Connecting Rod for Small Engines.

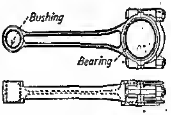

FIG. 154.—Connecting Rod of Automobile Engine.

The **maximum inertia stress** in a connecting-rod shank may be closely approximated by use of the following formulas:

For round rods, $f' = l^2wv^2/(0.098d^3 \times 16gR)$, where f' = stress due to inertia, lb per sq in.; w = weight of 1 in. length of rod, lb; v = velocity of crank pin fps; g = 32.2; R = crank radius, ft; d = mean diam of rod, in. For rectangular rods, $f' = l^2wv^2/(0.167bh^2 \times 16gR)$, where b = thickness of rod section, in., and h = height of rod section, in.

Connecting-rod ends as in Fig. 166 should have their bolts designed such that each may take ½ the maximum load on the cap with a stress of 5,000 lb per sq in. for wrought iron and 6,000 lb per sq in. for steel. In double-acting engines, the maximum load producing tension in the bolts may be occasioned by the internal pressure in the cylinder or the inertia of the reciprocating masses. In single-acting gas engines, the load on the bolts is caused by the inertia forces. **Strap ends** as shown at the crank-pin end of the rod in Fig. 152 should have the side straps designed to carry ½ the load, with a limiting

Hantman (*loc. cit.*) recommends that new chains be marked with prick-punch marks so that the distance between marks is 3 ft when the chain hangs freely. Annealing should be carried out where the stretch is 1 in. in 3 ft or if the chain shows a work-hardened condition. If the stretch is greater than this amount and the links bind, that portion of the chain should be scrapped. After repair or anneal, chains should be proof-tested. Chains that show gouge marks, cracks, bent links, excessive wear, or a tendency of the welds to open should be replaced. The safe load should be reduced for worn chains to compensate for wear.

For proportions of chain sheaves, see p. 833.

Dimensions of circular rings used at the ends of sling chains, (American Chain Co.) are as indicated in Table 88.

Crane Hooks. Since crane hooks act essentially as curved bars in bending, stresses in these hooks may be calculated by curved bar theory (Timoshenko, "Strength of Materials," Part 2, p. 423). For irregular cross sections as used in crane hooks, the graphical method described in this reference may be employed.

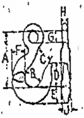

FIG. 142. Sling Hook.

Dimensions of standard sling hooks as made by American Chain and Cable Co. for the various chain sizes are given in Table 109 (dimensions refer to Fig. 142).

ENGINE DETAILS

Cylinders

The wall thickness, inches, of a cylinder subjected to internal pressure, P, pounds per square inch, is $t = PD/2f$, where D = diam of bore, in.; f = allowable stress in the cylinder wall; $f = 6{,}000$ for cast iron, 15,000 for steel. When P is higher than $f/5$ (in steel hydraulic-press cylinders for $P > 3{,}000$), the cylinder walls may be proportioned for strength by Lamé's formula (see p. 446). With *low pressures*, the *minimum* thickness of the wall for cast-iron cylinders is: $t = D/50 + 0.4$ in., when cast vertically; $t = D/50 + 0.5$ in., when cast horizontally.

through a succession of very small clearances c formed by rings fitting alternately in grooves in the stator and rotor. These rings are usually composed

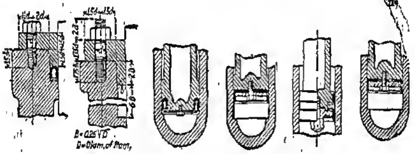

FIG. 157. FIG. 158. FIG. 159. FIG. 160. FIG. 161. FIG. 162.
Packings for Hydraulic Cylinders.

of short brass strips with clearance between their ends in order to preve
them from being forced out by expansion when heated. The clearance edg
of the rings are made 0.01 to 0.015 in. thick. The number of rings n require
to limit the leakage of steam to a given weight per second may be determine
from the formula

$$n = [40p - 2{,}600(w/a)]/[540(w/a) - p]$$

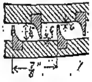

FIG. 163.

where p = absolute pressure of steam, lb per sq in., w = permissible leakage of steam, lb per sec, and a = cross-sectional area of the steam passage at the clearance rings, sq in. This formula is derived from a chart given in Morrow's "Steam Turbine Design," p. 293.

Example. Let dummy piston circumference = 70 in.; pressure before passin
through labyrinth = 180 lb per sq in. abs; pressure after passing labyrinth = 8
lb abs; clearance c = 0.01 in.; leakage w not to exceed 0.7 lb per sec. Here a = 7
× 0.01 = 0.7 and w/a = 0.7/0.7 = 1. Substituting in formula, number of rings fo
180 lb = 13; also number of rings for 85 lb = 2; whence, number of rings for leakage
of 0.7 lb per sec between the two pressures = 13 − 2 = 11.

Conical pistons for use in vertical engines may be proportioned for ngth according to the formulas given by Kraft (*Proc. I.C.E.*, 127, p. 259):

$$T = p(R^2 - x^2)/2fx \sin a; \quad t = px'/f \sin a$$

ere p = steam pressure, lb per sq in.; f = maximum allowable stress, lb sq in. (= 3,000 for cast iron and 9,000 for steel); T and t = minimum

Piston rings up to 20 in. diam may be made to the forms and propor-ons given in Figs. 146 and 147 and Table 91. The eccentric rings give a ore uniform pressure against the cylinder walls. This pressure should 3 to 5.5 lb per sq in.; in high-pressure compression up to 7 lb per sq in.

The strength of the piston ring may be estimated from, $f = 3pA^2/B^2$ or A^2/F^2, where f is the stress in pounds per square inch in the section opposite · The length D, in., through which the ring must be sprung to produce

through a succession of very small clearances c formed by rings fitting alternately in grooves in the stator and rotor. These rings are usually composed

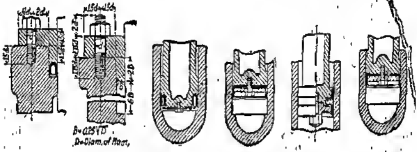

FIG. 157. FIG. 158. FIG. 159. FIG. 160. FIG. 161. FIG. 162.
Packings for Hydraulic Cylinders.

of short brass strips with clearance between their ends in order to prevent them from being forced out by expansion when heated. The clearance edges of the rings are made 0.01 to 0.015 in. thick. The number of rings n required to limit the leakage of steam to a given weight per second may be determined from the formula

$$n = [40p - 2{,}600(w/a)]/[540(w/a) - p]$$

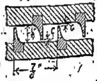

FIG. 163.

where p = absolute pressure of steam, lb per sq in., w = permissible leakage of steam, lb per sec, and a = cross-sectional area of the steam passage at the clearance rings, sq in. This formula is derived from a chart given in Morrow's "Steam Turbine Design," p. 293.

Example. Let dummy piston circumference = 70 in.; pressure before passing through labyrinth = 180 lb per sq in. abs; pressure after passing labyrinth = 85 lb abs; clearance c = 0.01 in.; leakage w not to exceed 0.7 lb per sec. Here a = 70 × 0.01 = 0.7 and w/a = 0.7/0.7 = 1. Substituting in formula, number of rings for 180 lb = 13; also number of rings for 85 lb = 2; whence, number of rings for leakage of 0.7 lb per sec between the two pressures = 13 − 2 = 11.

in.; E = modulus of elasticity in tension = 30,000,000 for mild steel; S = elastic limit of material = 30,000 lb per sq in. for mild steel.

A suitable design of a **piston-rod end** is shown in Fig. 148 and Table 92.

Crossheads

Engine crossheads of the **wing type** may have the features of construction shown in Fig. 149. The **box type** of crosshead may be designed as shown in Fig. 150. The substitution of pin shoulders on the crosshead and straight bores in the box for the taper construction reduces the cost of machining. The shoulders should bear on the face of the side opposite to which the nut

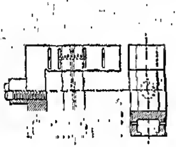

Fig. 149.—Wing Type of Crosshead.

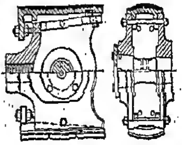

Fig. 150.—Box Type of Crosshead.

holding the pin is seated in order that screwing up the nut will not tend to bind the connecting-rod end in the box and thus cause heating. It is well to flatten the top and bottom portions of the pin where wear is a minimum to prevent the pin wearing to an oval shape. It is sometimes the practice to give the pin a quarter turn occasionally to promote more uniform wear. In locomotive and marine service, the type of crosshead shown in Fig. 151 is frequently used.

Crosshead Pins. In steam-engine practice, the crosshead pin is designed for a bearing pressure of 1,000 to 1,500 lb per sq in. According to Barr, American practice in proportioning crosshead pins is as follows: $dl = CA$, $l = Kd$; where d = pin diam in.; l = bearing length of pin, in.; A = piston area, sq in., C = 0.08 (0.07) for high (low) speeds, and K = 1.25 (1.3) for high (low) speeds.

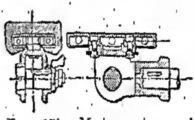

Fig. 151.—Marine-engine and Locomotive Type of Crosshead.

Shoes. The area of the shoes for stationary steam-engine crossheads should be such as to limit the maximum pressure to from 25 to 40 lb per sq in. The total maximum pressure of the crosshead shoes on the guide is $P \tan a$, where P = maximum steam-pressure load behind the piston, lb, and a = maximum angle of connecting rod with engine center line.

In **marine practice**, the area of the shoes, according to Bauer, is based in the following limiting pressures: 55 to 65 lb. per sq in. for cargo and slow-running passenger vessels; 65 to 80 lb per sq in. for mail steamers.

In **locomotive practice**, the limiting pressure on the crosshead shoe is about 85 lb per sq in.

Connecting Rods

Connecting rods for **locomotive** service may be made to the form shown in Fig. 152. For **small stationary engines**, rods of the form shown in Fig. 153 are used.

Table 95. Crank Angles and Piston Positions for Connecting Rods of Different Lengths

Fig. 164, the dead centers are unsymmetrical and the stroke is greater than $2r$, having the value

$$s = \sqrt{(l+r)^2 - h^2} - \sqrt{(l-r)^2 - h^2}$$

Determination of the Velocity of the Reciprocating Parts. The *velocity of the reciprocating parts is*

$$c = v\left(\sin\alpha + r\sin 2\alpha/2l\sqrt{1-\frac{r^2}{l^2}\sin^2\alpha}\right) = v(\sin\alpha + r\sin 2\alpha/2l) \text{ approx.}$$

when the center lines of the piston rod and crankshaft lie in the same plane. The ratio c/v is the tangential factor; Table 96 gives the values of velocities corresponding to various crank angles. When, however, the crank rotates about a center off the center line, as in Fig. 164 (offset cylinder), the above formula does not hold, and the graphical solution of Fig. 165 may be resorted

stress of 5,000 to 6,000 lb per sq in. The ends are made 1 to 1.6 times the thickness of the sides for both milled and strap ends.

Stuffing Boxes.

(For packings see p. 896)

The axial flow q of a liquid or gas through the clearance between a shaft and bushing can be estimated in cubic inches per minute.

$$q = 0.00108(1000c)^3dp/\mu l,$$

where c is the radial clearance in inches (half the diametral difference); p is the pressure drop across the bushing, lb per sq in.; l and d are the length and diameter of the bushing, in.; μ is the absolute viscosity of the liquid or gas, poises.

Stuffing boxes of the ordinary **bolted flange type** suitable for steam engines may be proportioned as shown in Fig. 155, where d = rod diam, in.; $d_1 = 1.22d + 0.6$ in.; $l_1 = 0.4d + 1$ in.; $l_2 = d + 1$ in.; $l_3 = 0.75l_2$;

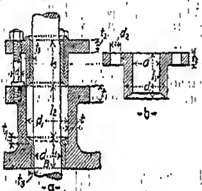

Fig. 155.—Bolted Flange Type.

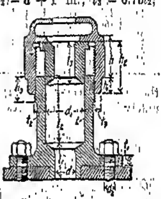

Fig. 156.—Screw Type.

Stuffing Boxes.

d_2 = bolt diam = $0.12d + \frac{1}{2}$ in. when 2 bolts are used, = $1.6(0.12d + \frac{1}{2}$ in.$)/\sqrt{n}$ where the number of bolts n is greater than 2; $t = 0.1d + 0.6$ in.; $t_1 = 1.4t$; $t_2 = t$; $t_3 = 0.04d + 0.2$ in. (not to exceed $\frac{1}{2}$ in.); $t_4 = 0.1d + 0.13$ in. (not to exceed 1 in.). All glands are to be of brass.

The screw type of stuffing box is not recommended but may be made as shown in Fig. 156, with

$d_1 = 1.3d + 0.6$ in.	$l_3 = 0.6d + 1$ in.	$h = 0.6d + 1$ in.
$d_2 = 0.15d + 0.5$ in.	$t = 0.1d + 0.3$ in.	$h_1 = 0.14d + 0.4$ in.
$l_1 = 0.4d + 1$ in.	$t_1 = 0.15d + 0.5$ in.	$h_2 = 0.67d + 1.2$ in.
$l_2 = d + 1.5$ in.	$t_2 = 0.13d + 0.4$ in.	$h_3 = 0.3d + 0.7$ in.

The gland is of brass.

Packings for hydraulic cylinders may be proportioned as shown in Figs. 157 and 158. The construction shown in Fig. 158 is adapted to pressures of 2,500 to 3,000 lb per sq in., and **hemp packing** is used.

Sometimes the ram of the press cylinder is **packed with leather**, as shown in Figs. 159 to 162. The proportions may be as given in Table 93. For high-pressure and superheated steam, stuffing boxes are usually provided with metallic packing.

Labyrinth Packing. Leakage past dummy or balance pistons of steam turbines of the Parsons type may be reduced to a small amount by a labyrinth packing (Fig. 163), where the steam pressure is throttled down by passing

this force is obtained by subtracting from the pressure on one face the corresponding pressure on the other face of the piston. In Fig. 167 are shown the indicator cards *ABCD* and *A'B'C'D'* for the forward and return strokes of a single-cylinder double-acting steam engine; the total pressures are given by the curves *abc* and *a'b'c'*. In Fig. 168 the indicator card *ABCDEF* of a single-cylinder, single-acting, four-cycle Diesel engine is shown.

Table 96. Tangential Factors and Piston Velocities

(Tangential pressure on crank = resultant horizontal pressure times tabular quantity. Forward stroke is toward crankshaft. Wrist-pin velocity = crank-pin velocity times tabular quantity.) Calculated from $\sin a + \dfrac{r \sin 2a}{2l\sqrt{1 - \frac{r^2}{l^2}\sin^2 a}}$

The inertia force of the reciprocating parts per square inch of piston area is obtained by multiplying the mass of the parts per square inch of piston area (piston, piston-rod, crosshead, and 0.35 to 0.45 of the connecting rod) by the acceleration of the piston (see Table 97). It is represented by the ordinates of the curves *xyz* and *x'yz'* for the forward and return strokes, respectively. The *ordinates between the total steam or gas pressure and the inertia curves* (p_1, p_2, p', and p'') give the resultant pressures acting on the piston along the center line of the engine.

Crank-Gearing

Analysis of the Motion of the Reciprocating Parts. Let r = crank radius, in.; R = crank radius, ft; $s = 2r$ = stroke, in.; l = length of connecting rod, in.; x = displacement of piston from head end dead center, in.; a = crank angle corresponding to x; b = connecting-rod angle corresponding to x; v = crank-pin velocity, fps; c = piston velocity, fps; N = rpm of the crank. Then, when the center lines of the piston rod and crankshaft lie in the same plane,

$$x = r(1 - \cos a) + l(1 - \cos b) = r\left(1 - \cos a + \frac{r}{2l}\sin^2 a\right), \text{ approx.}$$

Table 94. Piston Positions for Various Crank Angles

(From beginning of stroke toward crankshaft. To find distance of piston from beginning of stroke, multiply tabular value by length of stroke.)

Calculated from $\frac{x}{2r} = \frac{1}{2}(1 - \cos a) + \frac{l}{2r}\left(1 - \sqrt{1 - \frac{r^2}{l^2}\sin^2 a}\right)$

Table 94 gives correct piston positions corresponding to various crank angles. Table 95 gives also crank angles corresponding to various piston positions.

When, however, the center line of motion of the reciprocating masses is located a distance h from the center of rotation of the crank, as shown in

moving masses; and the areas *DEF* and *HAB* represent the energy per square inch of piston area liberated in the retardation of the moving masses for the production of useful work in the driven unit.

In the case of multicylinder engines, the tangential effort curves for each cylinder are superimposed, properly shifted with respect to each other, corresponding to the angular location of their respective cranks.

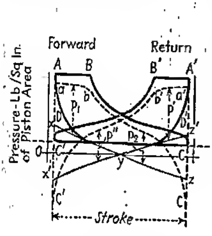

Fig. 167.—Indicator Cards of Double-acting Steam Engine.

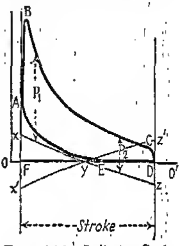

Fig. 168.—Indicator Card of Single-acting Diesel Engine.

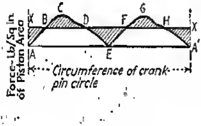

Fig. 169.—Tangential Force at Crankpin for Steam Engine of Fig. 167.

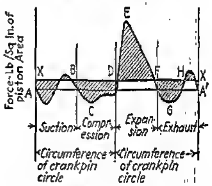

Fig. 170.—Tangential Force at Crankpin for Diesel Engine of Fig. 168.

Determination of Flywheel Weight. Let M = mass of wheel rim; W = weight of wheel rim, lb; v_1 = maximum linear rim velocity, fps; v_2 = minimum rim velocity, fps; $v = \frac{1}{2}(v_1 + v_2)$ = average rim velocity, fps; $k = (v_1 - v_2)/v$ = coefficient of velocity fluctuation; D = mean diam of rim, ft; N = rpm; A = piston area, sq in; E_m = energy represented by area *BCD* or *FGH* or *DEF* (Fig. 169) = maximum energy in ft-lb per sq in. of piston area which must be absorbed or liberated by the wheel rim with velocity variation between v_1 and v_2. Then

$$E_m \times A = M\frac{v_1^2}{2} - M\frac{v_2^2}{2} = \frac{W}{g}kv^2 = \frac{kWD^2N^2}{11,744}; \text{ or } W = \frac{11,744E_mA}{kD^2N^2}$$

About $\frac{9}{10}$ W may be placed in the rim to account for the flywheel effect

Crank Gearing

Analysis of the Motion of the Reciprocating Parts. Let r = crank radius, in.; R = crank radius, ft; $s = 2r$ = stroke, in.; l = length of connecting rod, in.; x = displacement of piston from head end dead center, in.; a = crank angle corresponding to x; b = connecting-rod angle corresponding to x; v = crank-pin velocity, fps; c = piston velocity, fps; N = rpm of the crank. Then, when the center lines of the piston rod and crankshaft lie in the same plane,

$$x = r(1 - \cos a) + l(1 - \cos b) = r\left(1 - \cos a + \frac{r}{2l}\sin^2 a\right), \text{ approx.}$$

Table 94. Piston Positions for Various Crank Angles

(From beginning of stroke toward crankshaft. To find distance of piston from beginning of stroke, multiply tabular value by length of stroke.)

Calculated from $\frac{x}{2r} = \frac{1}{2}(1 - \cos a) + \frac{l}{2r}\left(1 - \sqrt{1 - \frac{r^2}{l^2}\sin^2 a}\right)$

Table 94 gives correct piston positions corresponding to various crank angles. Table 95 gives also crank angles corresponding to various piston positions.

When, however, the center line of motion of the reciprocating masses is located a distance h from the center of rotation of the crank, as shown in

Nearly all governors depend for their action upon centrifugal force, and consist of a pair of masses rotating about a spindle driven by the prime mover and kept from flying outward by a controlling force, generally applied by springs. With an increase in speed, this controlling force is overcome and the masses move outward and this motion is transmitted to valves supplying the prime mover with its working fluid or fuel. In small machines, the governor acts directly upon the regulating valve or valves, while in large machines the governor moves small controlling valves admitting fluid under pressure into operating cylinders actuating the main governing valves (see also p. 218).

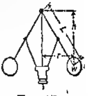

FIG. 172.

Conical Pendulum Governor (Fig. 172). In this governor, invented by Watt, the revolving masses are balls attached to a vertical spindle by link arms, and the controlling force consists of the weights of the balls themselves. There is a definite ball position for any particular speed, and the governor is said to be "static." For any position of the balls, the height of the cone of revolution of the balls and their arms is h (in.) $= 35{,}200/n^2$, where n = rpm. The sensitiveness of this governor, or the sleeve movement for a given change in speed, rapidly falls off as n increases.

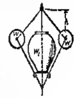

FIG. 173.

Loaded Governor. The **Porter governor** (Fig. 173) is a Watt governor with the addition of a heavy movable weight surrounding the spindle. For a given variation of speed, the height h (in.) is greater than with the Watt governor, being, when the four arms are of equal length, $h = [(w + w_1)/w] \times (35{,}200/n^2)$, where w = weight of one ball and w_1 = weight surrounding spindle, both in pounds. This type of governor can be run at much higher speeds than the Watt, and it is much more powerful with the same weights of balls.

Crossed-arm Governor. This is a conical pendulum governor in which each arm is suspended from a pin placed at the opposite side of the spindle to that of its ball. By proper proportioning, the balls may be made to move along an approximately parabolic path, and the height h made practically constant for the whole range of the governor, resulting in extreme sensitiveness.

Spring-loaded governors are those in which the controlling force is wholly or partly produced by springs. This permits the use of a horizontal or inclined axis of rotation.

Shaft governors consist essentially of a wheel keyed to the main shaft of the engine and carrying weights pivoted near its circumference, which are free to move outward under the influence of centrifugal force, this tendency being resisted by springs. In steam engines, the movement of the weights is communicated by links to an eccentric, thus varying the travel of the valve.

In **inertia shaft governors,** a weight arm is so pivoted and has its weight so distributed that its inertia assists in making the eccentric adjustment, and the more sudden the change in load the greater the assistance it renders. Thus, when the engine speeds up the weight tends to rotate at its old speed by reason of its inertia, and hence lags behind the wheel. Also, if the load is suddenly increased, the engine will slow down, but the weight arm will continue at its old speed, gaining on the wheel and again assisting the centrifugal force in altering the position of the eccentric with respect to the crank. In the Rites inertia governor, the weight arm is a long bar with heavy ends which is pivoted off its center to a pin some distance from the

to. AH is the center line of the piston rod produced, AP is the connecting rod, OP the crank with center at O. Draw OQ at right angles to AH. For any position AP of the connecting rod cutting OQ in E, the length OE represents the velocity of the reciprocating parts to the same scale to which OP

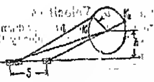

Fig. 164.

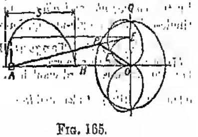

Fig. 165.

represents the crank-pin velocity. The graphical construction of Fig. 165 shows how to construct velocity ellipses for the whole revolution.

Determination of the Acceleration of the Reciprocating Parts. The acceleration p of the reciprocating parts is given by the equation

$$p = v^2(\cos a + r \cos 2a/l)/R, \text{ approx}$$

when the centerlines of the pistons and crankshaft lie in the same plane.

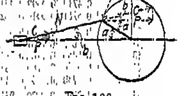

Fig. 166

Table 97 gives the values of the acceleration for different crank angles.

If the cylinder is offset, as in Fig. 164, the acceleration of the reciprocating parts may be found by the approximate formula

$$p = (v^2/R)[\cos a + (r/l) \cos 2a + h/l \sin a]$$

The inertia force in pounds per square inch of piston is $f = Mp/A = Wv^2(\cos a + r \cos 2a/l)/AgR = 0.00034WN^2R(\cos a + r \cos 2a/l)/A$, where W = total weight of reciprocating masses, lb; A = piston area, sq in. The value of W for any given engine is to be taken as the weight of the piston, piston rod, cross head, and a portion of the connecting rod. It is usual to include ½ to ⅔ the connecting-rod weight as part of the reciprocating masses. Values of $\cos a + (r/l) \cos 2a$ are given in Table 97.

Trooien shows that the weight of reciprocating parts for steam engines may be expressed by the formula $W = KD^2/SN^2$, where K = 1,370,000 to 3,400,000, with average value of 2,000,000; W = weight of parts, lb; D = cylinder diam, in.; S = stroke, in., and N = rpm.

Relation between the Force in the Line of Piston Travel and the Tangential Reaction at the Crank Pin. In Fig. 166, if P is the force in the line of piston travel, the force acting along the connecting rod is $C = P/\cos b$, and that on the guides $N = P \tan b$. The force tangent to the crank-pin circle at the crank pin is $T = C \sin (a + b) = P \sec b \sin (b + a) = P \sin a \cdot (1 + r \cos a/\sqrt{l^2 - r^2 \sin^2 a})$. Table 96 gives values of $\sec b \sin (b + a)$ for various values of l/r. They are equal to the tangential factors of piston velocities for different crank angles.

Determination of Flywheel Weight

Tangential Effort Curves. The total force on the piston at each instant is obtained from the indicator card. In the case of a double-acting engine,

between the limits of no steam supply and full steam supply. If this range is but a small percentage of n, the governor is said to be sensitive.

The **configuration of a governor** at any speed within its range may be determined, as in Fig. 174, a numerical example of a Watt governor being taken, in which $w = 10$ lb. Assuming the upper end of ball arm (Fig. 172) to be pivoted at the axis of spindle, $r^2 + h^2 = L^2 =$ constant, or, for any position, $r = \sqrt{L^2 - h^2}$. Now, $h = 35{,}200/n^2 = 9.78$ in. for 60 rpm, 7.19 in. for 70 rpm, and 5.5 in. for 80 rpm. Assuming radius $r = 10$ in. at 60 rpm, $L^2 =$ constant $= 195.6$, whence $r = 12$ in. at 70 rpm (for $h = 7.19$ in.) $= 12.8$ in. at 80 rpm. In Fig. 187, at any radius greater than 12.8 in., say 16 in., erect an ordinate AD. Calculate the values of $F = 0.00034rn^2w$ taking $r = 16$ in., $w = 10$ lb, and $n = 60$, 70, and 80, respectively, and lay these values off to scale, as AB, AC, AD. Draw OB, OC, and OD. Take $r_1 = 10$ in. by scale, and erect an ordinate cutting OB or the 60 rpm line at a; locate points b and c similarly, using radii r_2 and r_3 of 12 in. and 12.8 in., respectively, and connect a, b, and c by a smooth curve. This is the **curve of controlling force** of the governor, and the ball path radius for any intermediate speed may be obtained by suitably scaling AD, drawing a line from the desired speed value on this scale to O and dropping an ordinate to the radius scale from its intersection with the curve abc. When a tangent to any point makes a greater angle with OA than does a line drawn from O through the same point, the governor is stable throughout its range. The influence of friction can be readily seen by plotting $F + f$ and $F - f$ curves.

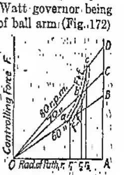

FIG. 174.

A governor is said to be **isochronous** (or astatic) when the speed of rotation is the same for all positions within its limits of movement. On account of the frictional resistances of the joints, however, the speed must always increase slightly before any additional centrifugal force is available, and this will move the weights to their extreme outward position; conversely, when the speed falls sufficiently for gravity or spring force to overcome the frictional resistance, the weights will move to their extreme inward position. In this way, the engine will fall into a state of speed oscillation or **hunting**, which is obviously objectionable and may be avoided by giving the governor a fair degree of stability, by reducing the frictional resistances as much as possible, and by the use of dashpots which offer great resistance to sudden movements but allow comparatively slow changes of position to take place freely.

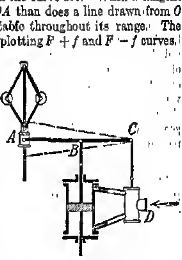

FIG. 175.—Governor Restoring Mechanism.

A **restoring mechanism** (Fig. 175) must be included between the governor sleeve and the pilot valve of a hydraulic relay to avoid "hunting." When the governor sleeve A rises, B forms at first a fixed fulcrum; pilot valve D is lowered and admits pressure fluid to the under side of the piston, which, in traveling upward, restores the pilot valve to its mid-position by using A as a fulcrum. This ensures for every speed of the turbine, in the steady state, a corresponding definite position of the valve, hence a definite output.

Table 97. Inertia Factors and Piston Accelerations

(Values of $\cos\alpha + r\cos 2\alpha/ly + r^2 \sin^2 2\alpha/4l^3y^3$, where $y = \sqrt{1 - \frac{r^2}{l^2}\sin^2\alpha}$. Algebraic signs relate to forward stroke; use opposite signs for return stroke.)

The tangential reactions at the crankpin can be obtained (p. 855) by multiplying the resultant pressure on the piston by the tangential factors for the various crank angles (see Table 96). In Fig. 169, curve *ACEGA'* shows the tangential reaction of the steam engine of Fig. 167 plotted against the travel of the crank, and Fig. 170 shows the same for the Diesel engine of Fig. 168.

In engine design, it is usual to construct the tangential effort curve from the cards obtained at normal or rated engine load and to assume that the engine is working against a constant and uniform torque. The uniform resisting torque is represented in Figs. 169 and 170 by *XX*, which is so located that the shaded areas above and below it are equal to one another. The areas *BCD* and *FGH* represent in foot-pounds per square inch of piston area the amount of energy which is effective in increasing the kinetic energy of the

$P = W/ld$ = unit pressure, lb per sq in.
N = rpm of a shaft.
μ = viscosity, in (lb)(sec)/(in.^{2}) units.
Z = viscosity, centipoises.
β = angle between load and entering edge of oil film.
c = coefficient for side leakage of oil.
h_0 = minimum film thickness.
$e = h_0/s$ = ratio of minimum film thickness to radial clearance.
f = coefficient of friction.
F = friction force, lb.
K = operating characteristic of a plain cylindrical bearing (see below).
K_f = coefficient for friction of a plain cylindrical bearing (see p. 867).
t_w = temp of bearing wall, deg F.
t_a = temp of air deg F.
t_1 = temp of oil film, deg F.

In bearings designed to work under conditions of greasy or semifluid *lubrication, the allowable mean intensity of pressure $P = W/ld$ is as* follows:

Hardened alloy steel on hardened steel	2,100
Hardened alloy steel on bronze	1,300
Alloy steel on bronze	850
Mild steel, smooth finish on bronze	550
Mild steel, ordinary finish, on bronze	400
Cast iron on bronze	400
Mild steel on cast iron	350
Mild steel on lignum-vitae with water lubrication	350

Fluid lubrication in plain cylindrical bearings depends on the viscosity of the lubricant and on its adhesion to the surfaces of the journal and the bearing. The radial clearance provided in the bearing forms, automatically, a wedge-shaped film between the journal and the bearing. The oil is entrained by the journal into the film. A hydrostatic pressure is created in the film, sufficient to float the journal and carry the load applied to it.

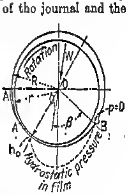

FIG. 1.—Journal Bearing with Perfect Lubrication.

The **minimum film thickness** h_0 determines the closest approach of the journal and bearing surfaces with complete lubrication (Fig. 1). The allowable closest approach depends on the degree of finish of these surfaces and on the rigidity of the journal and bearing structures. In practice, $h_0 = 0.00075$ in. is common in electric motors and generators of medium speed, with steel shafts in babbitted bearings; h_0 = 0.003 to 0.005 in. for large steel shafts running at high speed in babbitted bearings, (turbogenerators, fans) with pressure oil-supply for lubrication; h_0 = 0.0001 to 0.0002 in. in automotive and aviation engines, with very fine finish of the surfaces.

Figure 2 gives the ratio, e, of the minimum film thickness to the radial clearance for a plain cylindrical journal. The operating characteristic of the bearing is

$$K = \frac{P}{\mu N}\left(\frac{R-r}{r}\right)^2 \frac{1}{c}.$$

In Fig. 1, β is the angle between the direction of the load W and the entering edge of the load-carrying oil film, in degrees. The entering edge is at the

of the arms and other rotating masses. Acceptable values of k are as follows: pumps, $1/20$ to $1/30$; machine shops, $1/35$ to $1/40$; looms and paper mills, $1/40$; spinning mills, $1/60$; d-c generator (lighting), $1/150$; a-c generators, $1/300$.

Wittenbauer's Analysis for Flywheel Performance. The method does not involve more computation work than the one described above, but it is more accurate where the reciprocating parts are comparatively heavy. Wittenbauer's method avoids the inaccuracy resulting from the evaluation of the inertia forces on the reciprocating parts on the basis of the uniform nominal speed of rotation for the engine.

Let the crank-pin velocity be represented by v_r and the velocity of any moving masses (m_1, m_2, m_3, etc.) at any instant or phase be represented, respectively, by v_1, v_2, v_3, etc. The kinetic energy of the entire engine system of moving masses may then be expressed as

$$E = \tfrac{1}{2}(m_1v_1^2 + m_2v_2^2 + m_3v_3^2 \ldots) = \tfrac{1}{2}M_rv_r^2$$

where the single reduced mass M_r at the crank pin which possesses the equivalent kinetic energy is

$$M_r = [m_1(v_1/v_r)^2 + m_2(v_2/v_r)^2 + m_3(v_3/v_r)^2 + \ldots]$$

In an engine mechanism, sufficiently accurate values of M_r can be obtained if the weight of the connecting rod is divided between the crank pin and the wrist pin so as to retain the center of gravity of the rod in its true position; usually 0.55 to 0.65 of the weight of the connecting rod should be placed on the crank pin, and 0.45 to 0.35 of the weight on the wrist pin. M_r is a variable in engine mechanisms on account of the reciprocating parts, and should be found for a number of crank positions. It should include all moving masses except the flywheel.

The total energy E used in accelerating reciprocating parts from the beginning of the forward stroke up to any crank position can be obtained by finding from the indicator cards the total work done in the cylinder (on both sides of the piston) up to that time and subtracting from it the work done in overcoming the resisting torque, which may usually be assumed constant. The mean energy of the moving masses is $E_0 = \tfrac{1}{2}M_rv_r^2$.

In Fig. 171, the reduced weights of the moving masses $G_F + G_{rs}$ are plotted on the X axis corresponding to different crank positions. $G_F = gM_F$ is the reduced flywheel weight and $G_{rs} = gM_{rs}$ is the sum of the other reduced weights. Against each of these abscissas is plotted the energy E available for acceleration measured from the beginning of the forward stroke. The curve 0123456 is the locus of these plotted points.

This diagram possesses the following property: Any straight line drawn from the origin O to any point in the curve is a measure of the velocity of the moving masses; tangents bounding the diagram measure the limits of velocity between which the crank pin will operate. The maximum linear velocity of the crank pin in feet per second is $v_2 = \sqrt{2g \tan \alpha_2}$, and the minimum velocity is $v_1 = \sqrt{2g \tan \alpha_1}$. Any desired change in v_1 and v_2 may be accomplished by changing the value of G_F, which means a change in the flywheel weight or a change in the flywheel weight reduced to the crank pin. As G_F is very large compared with G_r and the point 0 cannot be usually located on the diagram unless a very large drawing is made, the tangents are best formed by direct calculation:

$$\tan \alpha_2 = \frac{v_r^2}{2g}(1 + k); \qquad \tan \alpha_1 = \frac{v_r^2}{2g}(1 - k)$$

where k is the coefficient of velocity fluctuation. The two tangents ss and tt to the curve 0123456, thus drawn, cut on the ordinate E_0 a distance ΔE. The reduced flywheel weight is then found to be

$$G_F(\Delta E)g/v_r^2k$$

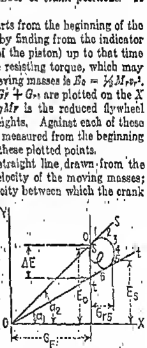

FIG. 171.—Analysis of Flywheel Performance.

Governors

Governors are mechanisms designed to maintain the speeds of prime movers (rpm) within reasonably constant limits, whatever the load may be.

be used. For crankpin bearings in punches and shears, mean pressures up to 3,000 lb per sq in. may be used.

Table 1. Current Practice in Mean Bearing Pressures

Type of bearing	Permissible pressure, lb per sq in. of projected area	*Type of bearing*	Permissible pressure, lb per sq in. of projected area
Diesel engines, main bearings	800–1,000	Gas engines, main bearings	500– 600
Crankpin	1,000–1,200	Crankpin	1,500–1,800
Wrist pin	1,800–2,000	Air compressors, main bearings	120– 240
		Crankpin	240– 400
Marine Diesel engines, main bearings	400– 500	Crosshead pin	400– 800
Crankpin	1,000–1,400	Aircraft engine crankpin	700–1,900
Marine line shaft bearings	25– 35	Centrifugal pumps	80– 100
Steam engines, main bearings	150– 500	Generators, low or medium speed	90– 140
Crankpin	800–1,500	Roll-neck bearings	1,500–2,000
Crosshead pin	1,000–1,800	Locomotive crankpins	1,500–1,700
Flywheel bearings	200– 250	Railway-car axle bearings	300– 350
Marine steam engine, main bearings	275– 500	Miscellaneous ordinary bearings	80– 150
Crankpin	400– 600	Light line shaft	15– 25
Steam turbines and reduction gears	70– 220	Heavy line shaft	100– 150

Length-diameter ratios are usually chosen between $l/d = 1$ and $l/d = 2$. In shorter bearings, the carrying capacity of the oil film is greatly impaired by the effect of side leakage. Longer bearings are used to restrain the shaft from vibration, as in line shafts, or to position the shaft accurately, as in

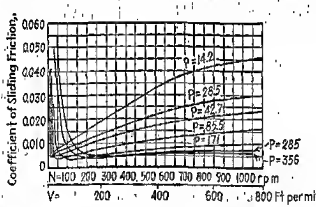

FIG. 4.—Variation of the Coefficient of Friction with Velocity and Pressure (in a 2¼ × 9¾-in. Bearing).

machine tools. In power machines, the tendency is toward shorter bearings. Typical values are as follows:

Turbogenerators, 0.8–1.5; stationary engines—for main bearings, 1.5–2.0, for crankpin bearings, 1; generators and motors 1.5–2.0; ordinary shafting—heavy, with fixed bearings, 2–3, light, with self-aligning bearings, 3–4; machine-tool bearings, 2–4.

For the **clearance between journal and bearing**, see Fits, p. 789. Medium fits may be used for journals running at speeds under 600 rpm, and

center of the shaft. In the Armstrong governor, a weight attached to the end of a laminated spring fixed to the hub of the governor wheel is acted on both by centrifugal force and inertia.

Helical **springs** for shaft governors may be calculated as follows: Let x = distance (ft) from center of gravity of weight to center of pin around which the weight turns; x_1 = distance (ft) from center of pin to point of attachment of spring. Then, pull P_1 on spring due to centrifugal force of weight W (lb) $= 0.00034WR_1^2n_1^2\,x/x_1$, where R_1 = distance (ft) from center of shaft to center of gravity of weight when running at n_1 rpm. Also, at n_2 rpm, $P_2 = 0.00034WR_2^2n_2^2x/x_1$. Then (see p. 486) P_2 = maximum tension (or compression) on spring, lb $= f\pi d^3/8D$, where d = diam of wire in spring, in.; D = mean diam of coil, in.; and f (safe) = 50,000. After obtaining d from the equation for a given diameter D and pull P_2, the number of active coils c required to give the necessary extension or compression S (in.) of the spring may be obtained from the formula $z = Cd^4S/S(P_2 - P_1)D^3$, where P_1 is the initial tension or compression on spring, lb and C = 12,000,000 for round steel wire. If with springs thus calculated the governing is too fine, reduce the number of active coils in order to stiffen spring and bring about a greater fluctuation in speed. If the governing is too coarse, a larger number of active coils is required. The **powerfulness** K of the two springs of a shaft governor depends upon the energy stored in the springs by extending them the amount S (from tension P_1 to tension P_2).

Hydraulic governors consist of an impeller acting as a centrifugal pump with oil as fluid; the oil pressure set up is applied to a piston subjected to a controlling force. With increase of speed, the piston moves until the controlling force is increased to balance the new oil pressure. Impellers with straight radial vanes are best, having a pressure characteristic practically independent of the volume of oil delivered by the impeller. The oil discharge in the operating mechanism does not therefore influence the governing pressure, which is nearly proportional to the square of the speed. For the same speed, the pressure varies as the square of the impeller diameter. The pressures generally used in oil governors vary from 10 lb in small machines to 60 lb per sq in. in large units. Lower pressures decrease friction losses in the impeller.

Stability, Isochronism, Hunting. The controlling force in a governor (whether gravity or that of springs) may be considered as a force F acting on each weight in the direction of the radius toward the axis of revolution. If w/g be the mass of the weight and r the radius of its center of gravity the governor will revolve in equilibrium when $F = 4\pi^2r(n/60)^2w/g = 0.00034rn^2w$. In order to ensure stability, F must increase more rapidly than r as the balls move outward. The frictional resistance to the action of a governor may be considered as a force f acting radially on each ball so that the whole controlling force is $F + f$ when the balls are moving out and $F - f$ when they are moving in. The corresponding speeds are given by the equation $F + f = 4\pi^2r[(n + \Delta n)/60]^2w/g$ and $F - f = 4\pi^2r[(n - \Delta' n)/60]^2w/g$. As a result of friction, the speed may change from Δn above to $\Delta' n$ below the normal speed n while the position of the balls is unchanged. It is apparent that a stable governor cannot maintain an absolutely constant speed in the engine it controls. If a change takes place in the load on a steam engine, it is necessary for the weights or balls to be displaced a certain amount in order to alter the steam supply, and the weights can retain their new position only at a changed speed. The maximum range of speed depends on that amount of change of n which is required to alter the configuration of the governor

shaft or flywheel journals in bronze bearing up to 84,000; in Babbitt bearing up to 224,000 and more for water-cooled journals. The value of WN/l can be determined for **high-speed bearings** by calculating H as follows (Lasche): For P from 15 to 215 lb per sq in., t from 68 to 212 F, V from 500 to 5,000 fpm; $H = 51.2V/(t - 32)$.

Representative **maximum values of H** for three types of medium- to high-speed bearing are given in the following table (after Lasche):

Heat Dissipation in Bearings
(Ft lb per min per sq in. of projected surface)

Temperature rise of bearing, deg F	60	90	120	150	180
Well-ventilated bearing	200	420	705	1470	[illegible]
Standard bearing, unventilated	110	220	360	560	830
Thin shell and housing, unventilated	40	60	80	105	140

If the calculated values of fPV exceed the radiating capacity at the maximum operating temperature, it is necessary to resort to artificial cooling. The highest bearing temperature permissible with normal lubricants is about 210 F. Bradford and Eaton gave the heat-dissipating capacity of bearings as $H = (T + 33)^2/K_h$, where $T = t_w - t_a$ and K_h is an experimental constant depending on the type of bearing and the air conditions surrounding it. For bearings of light construction in still air, $K_h = 55$. For bearings of heavy construction, well ventilated, $K_h = 31$.

Elements of Journal Bearings

Typical dimensions of solid and split **bronze bushings** are given in Table 2.

Table 2. Wall Thickness of Bronze Bushings, Inches

Diam of journal, in.	<1/4	1/4–1/2	1/2–1	1–1 1/2	1 1/2–2 1/2	2 1/2–4	4–5 1/2
Solid bushing, normal	1/16	3/32	1/8	3/16	1/4	3/8	1/2
Split bushing, normal	3/32	1/8	5/32	7/32	5/16	15/32	5/8
Solid bushing, thin	1/16	3/32	3/32	1/8	3/16	1/4	3/8
Split bushing, thin	1/16	3/32	1/8	3/16	1/4	3/8	1/2

Bronze bushings made from hard-drawn bronze sheets and rolled into cylindrical shape are made by the Cleveland Graphite Bronze Co. with a wall thickness of only 1/32 in. up to 1/2 in. diam and with a wall thickness of 1/16 in. for bearings from 1 in. diam up. The wall thickness of these bearings depends chiefly upon the strength of the material which supports them. Bushings of this type are pressed into place, and the bearing surface is finished by burnishing with a slightly tapered bar to a mirror finish. The allowable bearing pressures may exceed those of cast bronze shown in Table 1 by 10 to 20 percent.

Babbitt linings in larger bearings are generally employed in thickness of 1/8 in. or over and must be provided with sufficient anchorage in the supporting shell. The anchors take the form of dovetailed grooves or holes drilled in the shell and counterbored from the outside.

Improved conditions are obtained by sweating or bonding the Babbitt to the shell by tinning the latter, using potassium chlorate as flux. Tin-base Babbitts sweated to a bronze shell are sometimes used in thickness of only 1/32 in. and even less.

Figure 6 shows the principal types of bonded Babbitt linings. Figure 6*a* is for normal operating conditions. Figure 6*b* is for severer operating conditions.

PLAIN BEARINGS

BY

G. B. KARELITZ

Plain bearings, according to their function, may be

(1) **Journal bearings**, cylindrical in shape, carrying a rotating shaft.

(2) **Thrust bearings**, the function of which is to prevent lengthwise motion of a rotating shaft.

(3) **Guide bearings**, to guide a machine element in its lengthwise motion, usually without rotation of the element.

Friction in bearings depends on the type of lubrication employed (see p. 1899).

In exceptional cases of design, or with a complete failure of lubrication, a bearing may run dry. The coefficient of friction is then between 0.25 and 0.40, depending on the materials of the rubbing surfaces. With the **bearing barely greasy**, or when the bearing is well lubricated but the speed of rotation is very slow, boundary lubrication takes place. The coefficient of friction varies from 0.08 to 0.14. This condition occurs also in any bearing when the shaft is starting from rest.

Semifluid lubrication exists between the journal and bearing when the conditions are not such as to form a load-carrying fluid film and thus separate the surfaces. Semifluid lubrication takes place at comparatively low speed, intermittent or oscillating motion, heavy load, insufficient oil supply to the bearing (wick or waste lubrication, drop-feed lubrication). Semifluid lubrication exists also in thrust bearings with fixed parallel thrust collars, in guide bearings of machine tools, in bearings with copious lubrication where the shaft is bent or the bearing is misaligned, or where the bearing surface is interrupted by improperly arranged oil grooves. The coefficient of friction in such bearings is 0.02 to 0.08.

Fluid or **complete lubrication**, when the rubbing surfaces are completely separated by a fluid film, provides the lowest friction losses and prevents wear. A certain amount of oil must be fed to the oil film in order to compensate for end leakage and maintain its carrying capacity. Pressure lubrication, from a pump or gravity tank, is used, or automatic lubricating devices are provided in self-contained bearings (oil rings or oil disks), or the bearing is submerged in an oil bath (thrust bearings for vertical shafts).

Plain Cylindrical Journal Bearings

Notation.

R = radius of bearing, in.

r = radius of journal, in.

$s = R - r$ = radial clearance, in.

W = load on a bearing, lb.

l = length of bearing, in.

$d = 2r$ = diameter of journal, in.

In Fig. 8, W is the resultant force or load (lb) on the bearing or journal. The radial ordinates P_1, to the dotted curve, show the pressures (lb per sq in.) of the journal on the oil film due to the load when there is no axial groove, while the ordinates P_2, to the solid curve, show the pressures with an incorrectly located groove. Since there is no oil pressure near the groove, the permissible load W must be reduced or the film will be ruptured.

Groove dimensions (Fig. 9) are given by the following relations: $a = \frac{1}{3}$ wall thickness; $W_s = 2.5a$; $W_d = 3a$; $c = 0.5W_d$; $f = \frac{1}{16}$ in. to $0.5W_d$.

In order to maintain the oil film, the axial distributing groove should be placed in the unloaded sector of the bearing. The location of grooves in a variety of cases is shown in Figs. 10 to 26.

Horizontal Bearings, Rotational Motion

Direction of load known and constant.

Load downward or inside the lower 60 deg segment as in the case of ring-oiling bearings (Fig. 10).

Load at an angle more than 45 deg to the vertical center-line (Fig. 11).

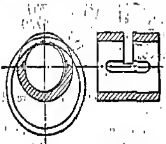

Fig. 10.

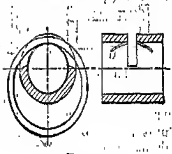

Fig. 11.

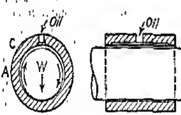

Fig. 12.

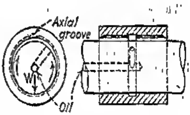

Fig. 13.

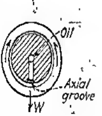

Fig. 14.

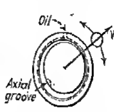

Fig. 15.

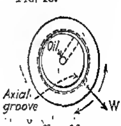

Fig. 16.

Force- or drop-feed oiling. The oil inlet may be anywhere within the no-load sector (Fig. 12).

Oil introduced through the center of the revolving shaft (Fig. 13).

Stationary journal and revolving bearing (Fig. 14).

place where the hydrostatic pressure is equal or nearly equal to the atmospheric pressure and may be at the location of the oil distributing groove B, or at the end of a machined recess pocket as at AA. For complete bearings *i.e.*, when the inner surface of the bearing is not interrupted by grooves—β may be taken as 60 deg (Fig. 2).

The coefficient c corrects for side leakage. There is a loss of load-carrying capacity caused by the drop in the hydrostatic gage-pressure p in the oil film from the mid-section of the bearing toward its ends; $p = 0$ at the ends. The value of c depends mainly on the length to diameter ratio l/d. Approximate values of c are as follows:

$l/d =$	3.0	2.0	1.5	1.0	¾	½	⅓
$c =$	0.80	0.70	0.60	0.50	0.35	0.20	0.10

The minimum film thickness $h_0 = e \times (R - r)$. Values of e are given in Fig. 2 for given values of β.

Example. A generator bearing, 6 in. diam $\times$ 9 in. long, carries a vertical downward load of 8,650 lb; $N = 720$ rpm. The diametral clearance of the bearing is $2s = 0.012$ in.; the bearing is split on its horizontal diameter, and the lower half is relieved 40 deg down on each side, for oil distribution along journal; the bearing arc is therefore 100 deg; with the load vertical, $\beta = 50$ deg. The absolute viscosity of the oil in the film is 23 centipoises (medium turbine oil).

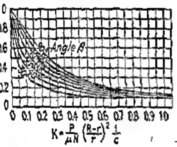

FIG. 2.—Minimum Film Thickness Ratio for a Plain Cylindrical Journal (for $K < 1$).

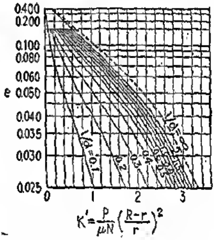

FIG. 3.—Minimum Film Thickness Ratio for a Plain Cylindrical Journal (for $K' > 1$).

$P = W/ld = 160$ lb per sq in.; $\mu = 23 \times 1.45 \times 10^{-7} = 33.4 \times 10^{-7}$ in (lb) (sec)/(in.^{2}) units. With $l/d = 1.5$, $c = 0.60$, and $K = 0.44$. From Fig. 2, with $\beta = 50$ deg, $e = 0.20$. The minimum film thickness $h_0 = e \times s = 0.66 \times 0.006 = 0.004$ in.

When the characteristic K is larger than 1.0 (heavy load, slow speed, low velocity), Fig. 3 should be used. In Fig. 3, the abscissas are K' which does not contain the coefficient c; the curves are drawn for various values of l/d, instead of values of β as in Fig. 2.

Allowable mean bearing pressures in bearings with fluid film lubrication are given in Table 1. If the load maintains the same magnitude and directions when the journal is at rest (heavily loaded shafts, heavy gears), the mean bearing pressure should be somewhat less than when bearings are loaded only when running. For the bearings of rope and chain sheaves, which turn intermittently, the mean bearing pressure is 350 to 850 lb per sq in.; where wear is not important, these values may be doubled. With crank (crosshead) pins of alloy steel running in bronze bushings, in ordinary steam engines, mean pressures from 700 to 1,000 (1,050 to 1,150) lb per sq in. may

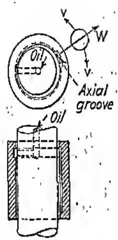

Fig. 21.

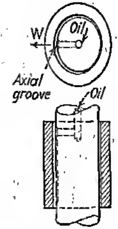

Fig. 22.

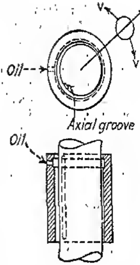

Fig. 23.

Bearings with Oscillatory Motion

Direction of load constant.

No oil film can be built up due to the small sliding velocity and unstable lubrication will exist. Axial grooves in the loaded sector distribute the lubricant to all parts of the bearing and avoid dry spots (Fig. 24).

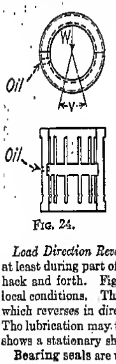

Fig. 24.

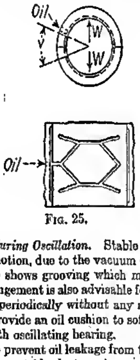

Fig. 25.

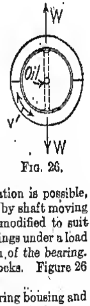

Fig. 26.

Load Direction Reversed during Oscillation. Stable lubrication is possible, at least during part of the motion, due to the vacuum caused by shaft moving back and forth. Figure 25 shows grooving which may be modified to suit local conditions. This arrangement is also advisable for bearings under a load which reverses in direction periodically without any rotation of the bearing. The lubrication may then provide an oil cushion to soften shocks. Figure 26 shows a stationary shaft with oscillating bearing.

Bearing seals are used to prevent oil leakage from the bearing housing and to protect the bearing from outside dust, water, vapors, etc. A drainage groove at the end of the bearing is effective to divert the oil passing through the bearing back into the oil well (Fig. 27*a*). The drain holes at the bottom

free fits for speeds over 600 rpm. Kingsbury suggests for these journals a diametral clearance $2s = 0.002 + 0.001d$ in. In journals running at high speed, $2s = 0.002d$ should be used in order to lower the friction losses in the bearing.

Figure 4 shows the dependence of the **coefficient of friction** f on the velocity and pressure for a journal bearing with oil-ring lubrication, as found by Stribeck for the stated unit pressures P. The descending branches of the curves give the friction in the semifluid range, at low speed. The minimum values of f are at the transition from semifluid to perfect lubrication (complete separation between bearing and journal surfaces). This transition takes place at lower speeds in bearings with a better finish of the bearing and journal surfaces. Figure 5 shows the influence of the bearing temperature on the value of f, observed by Stribeck for the bearing of Fig. 4, when the journal was run at 1,100 rpm.

The friction force F in plain journal bearings is $f \times W$. Also $F = K_f \mu N r l / \left(\frac{R - r}{r}\right)$ where μ is in (lb)(sec)/(in.^{2}) units. The value of K_f depends on the value of e (Figs. 2 and 3):

e =	1.0	0.9	0.8	0.7	0.6	0.5	0.4	0.3	0.2	0.1
K_f =	0.66	0.67	0.69	0.73	0.79	0.89	1.01	1.19	1.50	2.16

The **mechanical loss** in the bearing is $FV/33{,}000$ hp where V = the peripheral velocity of the journal, fpm. For high-speed bearings (turbines, generators), with a clearance ratio $(R - r)/r$ of .002, according to Soderberg, the loss is $0.00016 Zd^2 l (N/1000)^2$ hp, where Z is in centipoises.

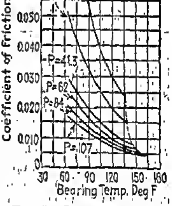

FIG. 5.—Influence of Bearing Temperature on the Coefficient of Journal Friction.

The **heat dissipation** L from the outside bearing wall in foot-pounds per minute, according to Karelitz, in quiet air, is $L = 0.184\, S(t_w - t_0)$, where S is the area of the bearing wall, sq in.; and t_w and t_0 are the respective temperatures of the wall and the ambient air, deg F. In an air draft, of velocity 500 fpm, the heat dissipation is 3 times as great. $S = (10 \text{ to } 15)dl$ for pillow blocks carrying bushings, and $S = (18 \text{ to } 25)dl$ for larger bearing-pedestals carrying cast-iron or steel bearing shells. In self-contained bearings (electric motors, line shafts, etc.) without artificial oil or water cooling, the dissipated heat is equal to the bearing losses; $L = FV$. The temperature rise of the wall can thus be determined.

For pedestals with steel bearing-shells with oil-ring lubrication operating without artificial cooling, the temperature of the oil film t_l is considerably higher than the temperature of the wall:

Temperature rise of the pedestal wall, $(t_w - t_0)$, deg F	20	30	40	50
Temperature of oil film above temperature of wall, $(t_l - t_w)$, deg F	20	24	27	30

The maximum **heat dissipation** H in foot-pounds per square inch of projected area of a journal per minute is given by $H = fWV/ld = fWN/3.82l$, where V = surface speed of journal, fpm. The values for WN/l may be taken as follows: *crankpin* in bronze bearing up to 210,000; in Babbitt bearing with low bearing pressures and short journals up to 494,000. *Main crank-*

Hardwood bearings containing lubricants are of lignum vitae which has a natural gum or hard maple which is impregnated with oil, grease, or wax. Lignum-vitae propeller bearings are used for ships, hard-maple bearings are used for loose pulleys, in textile machinery, wringer blocks.

Porous-metal bearings compressed from metal powders and sintered contain up to 35 percent of liquid lubricant. The porous metal generally consists of a 90–10 copper-tin bronze with 1½ percent graphite. These bearings do not require oil grooves since capillarity distributes the oil and maintains an oil film. If additional lubrication from an oil well should be provided, oil will be absorbed through the porous wall as required. For high temperatures where oil will carburize, a higher percentage of graphite (6 to 15 percent) is used.

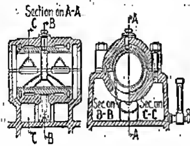

FIG. 31.—Split Bearing with One Chain. Main Crankshaft Bearing. Vertical Oil Engine.

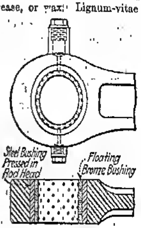

FIG. 32.—Floating Bushing. Big End Locomotive Main Rod.

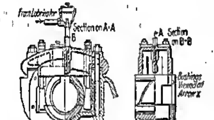

FIG. 33.—Crankshaft Main Bearing. Horizontal Steam Engine. Drop Feed Lubrication.

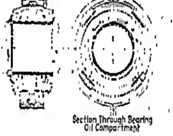

FIG. 34.—Large Turbine Bearing (Westinghouse). Self-aligning, with Additional Path for Cooling Oil in the Shell.

Porous-metal bearings are used where plain metal bearings are impracticable, due to lack of space or inaccessibility for lubrication, as in automotive generators and motors and vacuum-cleaner motors. Porous-metal bearings are manufactured by Bound Brook Oil-less Bearing Co.; Chrysler Corporation; Moraine Products Co., Dayton, Ohio; U. S. Graphite Corp., Saginaw, Mich.

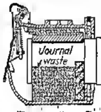

FIG. 35.—Car-wheel Journal Box with Oil-saturated Waste Packing in Lower Half.

Thrust Bearings

At low speeds, shaft shoulders or collars bear against flat bearing rings. The lubrication is semifluid, and the friction is comparatively high.

For die-cast automotive bushings, Heldt recommends the following proportions: $D = 1.2d$ for main crank bearings; $D = 1.2d$ for connecting-rod bearings; $t = 0.1d$; $e = 0.25d$; where d is the journal diameter, D the outside diameter of the bushing, t the thickness of the flange, and e the diameter of the anchorage lug.

General practice for the **thickness of Babbitt lining and shells** is as follows: FIG. 7, $b = \frac{1}{32}d + \frac{1}{8}$ in.; $S = 0.18$ in. for bronze or steel $= 0.2d$ for cast iron. FIG. 7a, $t = \frac{b}{2} + \frac{1}{16}$ in.; $W = 1.8t$; $W_1 = 2.2t$.

Solid bronze or steel bushings, when pressed into the bearing housing, must be finished after pressing in. Light press fits and securing by setscrews or keys are preferable to heavy press fits and no keying, since heavy pressure, especially in thin-walled bushings, will set up stresses which will

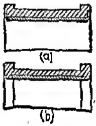

FIG. 6.

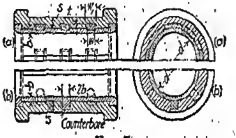

FIG. 7.

release themselves if bearings should run hot in service and will result in closing in on journal and scoring when cooling.

Uniform Load Distribution. Misalignment between journal and bearing should never be so great as to cause metallic contact. The maximum allowable inclination α of the shaft to the bearing is given by $\tan \alpha = 2s/l$.

Whenever the deflection angle of the bearing installation is greater than α, either the bearing length should be reduced or, if that is not feasible, the bearing should be mounted on a spherical seat to permit self-alignment.

As a general rule, fixed bearings may be used for l/d ratios up to 2 and self-aligning seats for l/d ratios from 3 to 4.

Oil grooves are of two kinds, axial and circumferential: the former distribute the oil lengthwise in the bearing; the latter distribute it around the

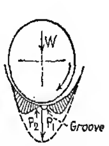

FIG. 8.

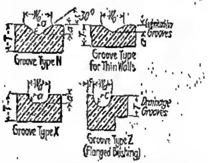

FIG. 9.—Lubrication and Drainage Grooves.

shaft at the oilhole, and also collect and return oil which would otherwise be forced out at the ends of the bearing. Grooves have often been put into bearings indiscriminatingly, with the result that they scrape off the oil and interrupt the film.

friction in these bearings varies from $f = 0.03$ at $P = 45$ to $f = 0.06$ at $P = 15$.

The performance of the bearing thrust rings is much improved by the introduction of grooves with tapered lands as shown in Fig. 37.[1] The lands extend on either side of the groove. The taper angle of the lands is very slight, so that a pressure-oil film is formed between the bearing ring and the collar of the shaft.

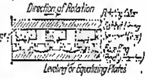

FIG. 41.—Kingsbury Thrust Bearings. (Developed Cylindrical Sections.)

For high speeds or where low friction losses and a low wear rate are essential, **pivoted segmental thrust bearings** are used (Kingsbury thrust bearing, or Michell bearing in Europe). The bearing members in this type are tiltable shoes which rest on hard steel buttons mounted on the bearing housing. The shoes are free to form automatically a wedge-shaped oil film between the shoe surface and the collar of the shaft (Figs. 38, 39, 40).

The minimum oil film thickness h_0 in., between the shoe and the collar, at the trailing edge of the shoe, is approximately $h_0 = 0.12\sqrt{\mu V l/P}$, where V is the velocity of the collar, on the mean diameter, fpm and $P = W/lb$. As indicated in Fig. 38, $b = l$ approx. The standard thrust bearings have six shoes. Load-carrying capacities of Kingsbury thrust bearings are given in Table 3.

The coefficient of friction in Kingsbury thrust bearings, referred to the mean diameter of the shoes, is $f = 2.7\sqrt{\mu V/lP}$. Figures 39 and 40 show typical pivoted segmental thrust bearings. They usually embody a system of rocking levers which are used for alignment and equalization of load on the several shoes (Fig. 41).

Sliding Bearings

All sliding bearings (Fig. 42) to wear true must have the sliding parts of nearly equal lengths. Bearings made in this way will be found not to wear out of true. Oiling is accomplished in several ways, an acceptable method being that shown in Fig. 43. Short slides *in many machine tools are lubricated by oil pads or direct oil application.* The weight of the table and work and thrust of the tool cause wear on the

FIG. 42.

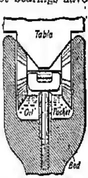

FIG. 43.

FIG. 44.

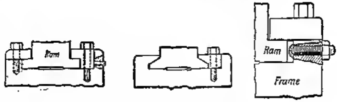

FIG. 45.

bottom and sides of the guides. To compensate for the wear in both directions, bearings are sometimes made V-shaped, as shown in Fig. 44.

Simpler sliding bearings in machine tools are made with provision for adjustment, as shown in Fig. 45, of which there are many modifications.

Load variable inside a given angle.

Figures 10, 11, 12, 13, and 14 are suitable, provided there is about 45 deg between the axial groove and the direction of the load W.

Rotating load.

For rotating shafts, a circumferential groove at the middle of the bearing and an axial groove on the no-load side (Fig. 15).

For stationary shafts and rotating bearings, a circumferential groove in the bearing and an axial groove on the no-load side. The oilhole is in the shaft at the mid-length of the bearing (Fig. 16).

Load direction uncertain.

Oil-ring bearings (Figs. 10 and 12) may be used although they have defects under certain load directions. With forced or drop feed, the oilhole enters a circumferential groove at the middle of the bearing and the axial groove is omitted (Fig. 17). Arrangements for introducing oil through the rotating shaft can be made.

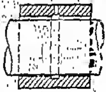

FIG. 17.

THE MECHANICS OF ROLLING CONTACT BEARINGS

Rolling contact between journal and bearing is produced by inserting rolling members between concentric surfaces of the stationary and moving elements.

If free rolling in two directions is required, the rolling elements must be balls; ... ction, the rolling elements may ... , provided always that all the c... tersect in one point of the main axis of rotation and that the (geometrical) sum of all the individual angular velocities is equal to the angular velocity of rotation around the main axis. These theoretical requirements for pure rolling cannot always be fulfilled.

In Fig. 1, the location of the intersecting point on the main axis of rotation determines the direction of the load which the bearing can support. If the

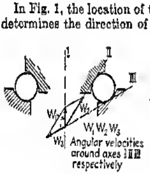

FIG. 1.

FIG. 2.

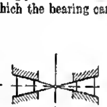

FIG. 3.

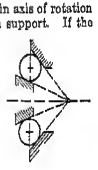

FIG. 4.

intersection is at infinity (Fig. 2), the load may be radial or annular. With intersection at the center of the bearing (Fig. 3), the loading is thrust or axial. With intersection in an intermediate position, (Fig. 4), the load is angular.

Notation.

B_r = Brinell hardness number.

D_i = inner race diameter, in.

d_1, d_2 = curvature diameters of two rolling bodies at their point of contact.

d_2', d_2'' = principal curvature diameters of a curved surface (at right angles to each other), in.

δ_r = curvature diameter of a substitute rolling body in contact with a flat surface, in.

ξd_r = diameter of the contact surface for balls or the width of the contact rectangle for rollers of length L, in.

E = modulus of elasticity for the material, lb per sq in.

of the groove must be ample for passage of the oil flow. An oil thrower mounted on the shaft is shown in Fig. 27*b*. The bearing housing may be provided with a single (Fig. 27*c*) or double collecting groove, or with brass or aluminum strip scrapers (Fig. 27*d*), to collect the oil creeping along the shaft.

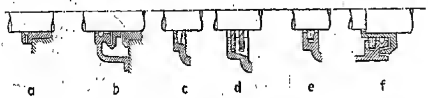

Fig. 27.—Sealing End Grooves.

For protection from dust, etc., felt packing rings are often used (Fig. 27*e*). The felt ring is soaked in oil to prevent charring by friction heat. In severe cases, additional protection by a labyrinth runner is very effective (Fig. 27*f*).

Line-shaft bearings are purchasable in standard sizes by steps of ¼ in. for the smaller diameters, and by steps of ½ in. for the larger sizes. **Hangers** for line-shaft bearings may be purchased in types permitting ceiling, floor, or wall suspension. Figure 28 shows bearings for mounting in line-shaft hangers.

Fig. 28.—Bearing for Drop Hanger with Oil Ring Lubrication.

Main Shaft Machine Bearings. Average practice in proportioning the diameters and lengths of headstock bearings in lathes is as follows:

Front bearings: $d = s/5$; $l = s/4$. Back bearings: $d = s/8$; $l = s/6$; where d(diam), l(length) and s(swing) are all in inches.

Types of bearings are shown in Figs. 29 to 35. They include the principal methods of lubrication and types of construction.

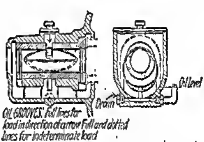

Fig. 29.—Ring-oiled Bearing Solid Bushing.

Oilless bearings (information by C. Claus, Bound Brook Oil-less Bearing Co.) is the accepted term for self-lubricating bearings containing lubricants in solid or liquid form in their material. Graphite is used as a solid lubricant in one group, and another group consists of porous structures (wood, metal), containing oil, grease, or wax.

Graphite-lubricated bearings (bridge bearings, sheaves, trolley wheels, high-temperature applications) consist generally of cast bearing bronze as a supporting structure containing various overlapping designs of grooves which are filled with graphite. The graphite is mixed with a binder, and the plastic mass is pressed into the cavities and baked to the hardness of a lead pencil; 45 percent of the bearing area is graphite. Drilled holes are also used for filling the bronze bearings with graphite in plastic form or with preformed graphite plugs. Strip bronze with indentations or grooves filled with graphite is used in sheet form or rolled to a butted cylindrical bushing. These bearings are manufactured by Bound Brook Oil-less Bearing Co.; Cleveland Graphite Bronze Co.; Merriman Bros., Boston.

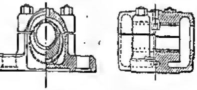

Fig. 30.—Rigid Ring-oiling Pillow Block (Link-Belt Co.).

The maximum compression stress p_{max} in a roller with diameter d_r and length L (for $L > d_r$) and in the flat surface with which it is in contact can be written according to Hertz

$$p_{max} = 4P_o/\pi\xi d_rL$$
$$(\xi d_r/2)^2 = 4P_o d_r(1 - 1/m^2)/EL$$
$$p^2_{max} = P_oE/(\pi Ld_r)(1 - 1/m^2) = 0.35P_oE/Ld_r$$
$$\xi = 4(1 - 1/m^2)p_{max}/E \text{ (with } 1/m = 0.3)$$

By introducing the mean stress p_m in the pressure area,

$$p_m = 2P_o/\pi\xi d_rL = \pi p_{max}/4$$
$$\xi = 4.64p_m/E \text{ (with } 1/m = 0.3)$$

If k_o is the specific load, lb per sq in., produced by P_o upon a rectangle with the area f surrounding the rolling element,

$$k_o = P_o/f = P_o/d_r^2 = [p_m(\xi d_r)^2\pi/4]/d_r^2, \ (= 14.3p_m^3/E^2, \text{ for balls})$$
$$k_o = P_o/f = P_o/d_rL = p_m\xi d_rL/d_rL, \ (= 4.64p_m^2/E, \text{ for rollers})$$

For materials following Hooke's law and for stresses within the elastic limit, the specific load capacity of balls does not vary exactly with d^2. Smaller balls have a relatively higher load capacity as indicated by the relation $P_o = k_od^2/1 + .002d)$. In rollers the relative load capacity appears to be unaffected by the diameter. For values of p_m and k_o, see under "Static Load Capacity."

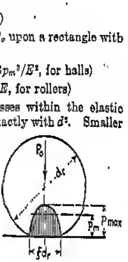

FIG. 5.

Stresses in Axial or Thrust Bearings. If each rolling element (ball or roller) carries an equal share of the axial load P_a, then $P_a = fk_on$.

The coefficient of utilization η_a of the axial bearing is given by $\eta_aF = nf$, where F is the ring area of the bearing $= \pi/4(D_o^2 - d_i^2)$. η_a is less than 1 in bearings with retainers and equals 1 in full-type bearings. The previous equation can then be written $P_a = \eta_aFk_o$ and the specific axial bearing load $p_a = P_a/F = \eta_ak_o$.

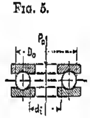

FIG. 6.

In order to ensure equal load distribution, the rolling elements must have uniform size and at least one of the supporting outside faces of the races should be spherical to permit of self-alignment.

The **influence of speed** on the load-carrying capacity of thrust bearings is particularly pronounced in ball thrust bearings. This is due to sliding and skewing of the balls driven by centrifugal force against the curved raceways in addition to the normally reduced dynamic load capacity.

If v is the mean velocity of the balls, in fps, the reduced thrust capacity P_a' lb, may be written as follows: $P_a' = 3.3P_a/(v + 3.3)$ where P_a is the static load capacity, lb. For instance, at 10 fps, $P_a' = 0.248P_a$.

Stresses in Radial or Annular Bearings. If the radial load P_r could be assumed to be supported by a flexibly yielding outer race, the load would be evenly distributed over all the rolling elements in the loaded half of the bearing and each element would support the load P_o. The specific radial bearing load p_r could therefore be written $p_r = P_r/D_iL = \eta_rk_o$.

Because of the comparative rigidity of the outer race, if the bearing is assembled with clearance and not under initial stresses, the rolling elements

For hardened-steel collars on bronze rings, with interrupted service, pressures up to 2,000 lb per sq in. are permissible; for continuous low-speed operation, 1,500 lb per sq in.; for steel collars on babbitted rings, 200 lb per sq in. In multicollar thrust bearings, the values are reduced considerably because of the difficulty in distributing the load evenly between the several collars.

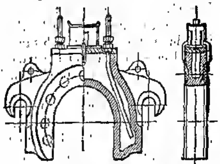

Fig. 36.—Horseshoe Bearing Ring for Marine Thrust Bearing.

Thrust bearings for marine service are sometimes made with adjustable horseshoe bearing rings as shown in Fig. 36 and with provision for water-cooling. The thrust collars are formed by grooving the shaft and have an outside diameter $D = 1.6d$ to $1.9d$, where d is the normal shaft diameter. The thickness of each collar $= w = 0.13d$ to $0.16d$, and the distance between collars $= s = 2w$ to $3w$. The number of collars required $= n = P/\pi d_1 bp$, where P = total thrust on bearing, lb; d_1 = mean diam of collar, in.; b = radial width of collar, in., and p = allowable bearing pressure, lb per sq in., as follows: for cargo steamers, $p = 40$ to 55; for passenger steamers, $p = 55$ to 80. According to Howarth, the coefficient of

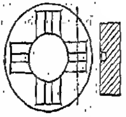

Fig. 37.—Thrust Collar with Grooves Fitted with Tapered Lands.

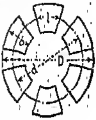

Fig. 38.—Kingsbury Thrust Bearing with Six Shoes.

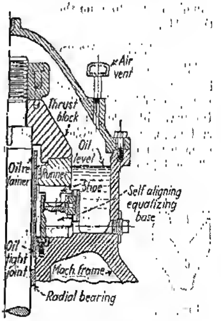

Fig. 40.—Half Section of Mounting for Vertical Thrust Bearing.

at rest, local permanent deformation interferes with subsequent smooth bearing operation.

With very slow uniform rotation, the non-brinelling static load may be exceeded by up to 30 percent because the permanent deformation results in cold-working of the material and produces a uniformly distributed change in the shape of the race surfaces.

The effect of race hardness upon the specific load factor k_o for short and long cylindrical rollers is shown in Table 1.

Table 1. Multipliers of Load Capacity with Varying Race Hardness

Brinell hardness No., kg per sq mm	Rockwell C hardness	Short solid rollers (Hyatt)	Long solid rollers, Bantam, needles
627	60	1.0	1.0
601	58	0.935	0.969
578	57	0.902	0.940
555	55	0.84	0.875
534	53	0.78	0.769
514	52	0.75	0.700
495	50	0.69	0.500

Although the dynamic load capacity changes comparatively little in the range above a Rockwell C hardness of 60, the static capacity depends greatly not only upon the surface hardness but also upon the hardness through a substantial depth of rolling elements and races.

The permissible mean stress p_m varies substantially in direct proportion with the Brinell hardness number B_r of races and rolling elements. In modern bearings, $p_m = 1422XB_r$ lb per sq in.

In ball bearings: $X = 0.85$ to 0.95.

In roller bearings with $L \lesseqgtr 2d$: $X = 0.6$ to 0.65.

In needle bearings with $L \gtreqless 4d$: $X = 0.375$–0.45 down to 514 Brinell hardness and drops gradually, reaching 0.325–0.375 at 495 Brinell.

The effect of high operating temperatures which reduce the hardness must be considered in selecting bearings of sufficient load capacities. The value of k_o of stainless-steel ball bearings even with a Rockwell C hardness of 60 (as compared with 63 to 64 for standard ball bearings) is only about 70 percent of k_o for standard ball bearings.

Examples. *Ball bearing.* A No. 307 Norma-Hoffman deep-groove radial bearing containing eight ½ in. balls, with races having 62–64 and balls having 63–65 Rockwell C hardness, has a static non-brinelling load capacity P_o per ball of 6,250 lb. The substitute radius d_r from formula (2) with a groove diameter of 0.510 in. and an inner race diameter of 1.75 in. is 0.765 in. The static $k_o = 6250/0.765^2 = 10{,}684$ lb per sq in. With $E = 30 \times 10^6$, $p_m^3 = 10{,}684E^2/14.3$ and the static $p_m = 876{,}000$ lb per sq in. This is equivalent to $0.92B_r \times 1422$ with a Brinell number $B_r = 667$ corresponding to an average race hardness of 63 Rockwell C.

The dynamic load capacity of the balls is substantially lower. For an average life of 2,500 hr according to the manufacturers' load ratings, P_o becomes 2,540 lb for 100 rpm and 1,240 lb at 1,000 rpm with k_o and p_m reduced accordingly.

Short Roller Bearings. A No. R-345-L (No. 309 S.A.E.) Norma-Hoffman cylindrical roller bearing with twelve ½ in. rollers of 0.425 in. effective length, with 62–64 Rockwell C races and 63–65 Rockwell C rollers, has a static non-brinelling capacity of 9,375 lb per roller. The substitute radius d_r from formula (1), with an inner-race diameter of 2.375 in., is 0.414 in. The static load $k_o = 9375/0.425 \times 0.414 = 54{,}300$ lb per sq in. With $E = 30 \times 10^6$, $p_m^2 = 54{,}300E/4.64$ and static $p_m = 593{,}000$ lb per sq. in. This is

Figure 9 illustrates the difference in catalogue ratings of three manufacturers for the same ball-bearing size with the same size and number of balls, but with different life expectancies.

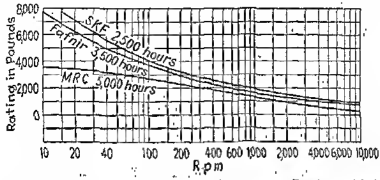

FIG. 9.—Ratings for No. 210 Single-row Deep-groove Bearings with Ten ½ in. Balls.

Figure 10 shows multipliers for catalogue ratings of five ball-bearing manufacturers to obtain bearing lives at loads other than those on which the catalog ratings are based [see Eq. (4)].

If both the load and speed of a bearing vary, an equivalent average load P_{av} at a speed n_s can be obtained from the equation

$$P_{av} = \sqrt[x]{r_1 n_1/n_s P_1^x + r_2 n_2/n_s P_2^x + \cdots r_n n_n/n_s P_n^x}$$

where r_1, r_2, etc., represent the time fractions; P_1, P_2, etc., the loads prevailing during each time fraction; and n_1, n_2, etc. are the rpm at those times. This value of P_{av} may be used in connection with Eq. (5).

Annular bearings with revolving inner races have a smaller number of stress reversals for the same rpm than when the outer races revolve. Therefore the life expectancy with outer race revolving is lower than with inner race revolving.

The type and size of the bearing determine this difference, and the manufacturers supply suitable correction factors for the ratings or speeds, which are always given for revolving inner races.

SKF gives, for outer races revolving, 90 percent of the carrying capacities of self-aligning ball bearings and 75 percent of the carrying capacities of all other bearing types. The multipliers for Bantam needle bearings range from 1.2 for small bearings up to 1.06 for large bearings.

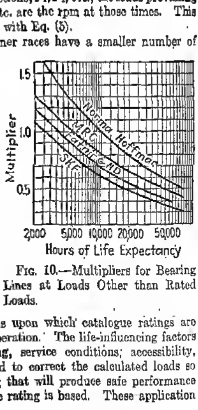

FIG. 10.—Multipliers for Bearing Lines at Loads Other than Rated Loads.

The ideal load and speed conditions upon which catalogue ratings are based do not prevail in normal field operation. The life-influencing factors of shock, temperature, pre-loading, service conditions, accessibility, and lubrication are therefore employed to correct the calculated loads so as to find from the catalogue a rating that will produce safe performance during the average life upon which the rating is based. These application

$1/m$ = Poisson's ratio
η_a and η_r = coefficients of utilization of bearings
k_0 = the specific load produced by P_o upon a rectangle of area which is d_r^2 for balls and d_rL for rollers, lb per sq in.
L = length of rolling element, in.
n = number of rolling elements.
P_a = static axial load capacity for a bearing, lb.
P_o = the load on a rolling element, lb.
P_r = static radial load capacity for a bearing, lb.
p_a = specific axial bearing load, lb per sq in.
p_r = specific radial bearing load, lb per sq in.
p_m = mean compressive stress for the contact area, lb per sq in.
p_{max} = maximum compressive stress for the contact area, lb per sq in.

To obtain the highest load-carrying capacity, the surfaces of races and rolling elements must be accurately finished with a high surface polish.

Individual Load Capacity of the Rolling Elements

The relative curvature of a rolling element in contact with the race determines the stresses and deformations of the contact surfaces when pressed together.

According to Hertz, the curvature diameter d_r of a substitute rolling body in contact with a flat surface can be used in place of the curvature diameters d_1 and d_2 of two rolling bodies in contact with each other.

$$1/d_r = 1/d_1 + 1/d_2 \tag{1}$$

If a ball of the diameter d_1 is in contact with a race having two principal curvature diameters (at right angles to each other) d_2' and d_2'', the diameter d_r of a substitute ball in contact with a flat surface may be written approximately as follows:

$$\frac{2}{d_r} = \frac{2}{d_1} + \frac{1}{d_2'} + \frac{1}{d_2''} \tag{2}$$

For concave surfaces, the signs in (1) and (2) are negative.

In order to keep d_r as large as possible in ball bearings, so as to increase the carrying capacity, the radii of the raceway grooves are kept as nearly equal to the ball radius as possible.

Under load, the race and rolling element flatten out at the contact surface. The area of this contact surface equals $(\xi d_r)^2\pi/4$ for balls and $\xi d_r L$ for cylindrical rollers, where ξd_r is the diameter of the contact surface for balls or the width of the contact rectangles for rollers of the length L and where d_r is the diameter of the substitute rolling element in contact with a flat surface.

The mean compression stress p_m, lb per sq in., for this contact area is

$$p_m = P_o/(\xi d_r)^2\pi/4 \text{ (for balls)} = P_o/\xi d_r L \text{ (for rollers)}$$

According to Hertz, the maximum compression stress p_{max} in a ball with diameter d_r and in a flat surface with which it is in contact is $1.5p_m$.

$$(\xi d_r/2)^3 = 1.5(1 - 1/m^2)P_o d_r/2E$$

Therefore

$$p^3_{max} = 1.5P_oE^2/\pi^3(d_r/2)^2(1 - 1/m^2)^2$$

For metallic bodies the value of $1/m$ may be taken as 0.3 and with $p_m = p_{max}/1.5$

$$\xi = 4.28p_m/E \text{ for balls}$$

The great majority of retainers are made from steel stampings. For high-speed-precision and ultra-precision bearings, carefully machined retainers are used, usually designed so that the ... the outside of the inner race. These high-speed ... made from fabric-reinforced phenol plastics.

Normal and Extreme Bearing Speeds. The speeds listed by the manufacturer apply usually only to standard bearing types. With precision and ultra-precision bearings, these speeds can be substantially exceeded (see Figs. 11 and 12). The limit speeds indicated apply to rotating inner races. For stationary inner races, the rpm shown must be multiplied by 0.6.

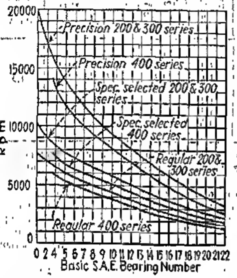

FIG. 11.—Limiting Speeds of Standard Ball Bearings (Single-row Deep-groove Angular and Duplex).

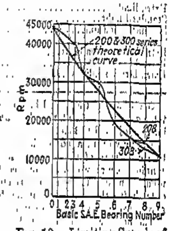

FIG. 12.—Limiting Speeds of Super-precision Bearings.

Friction of Rolling Contact Bearings

The total friction is composed of rolling friction, due to elastic deformation caused by the bearing loads, and of *sliding friction* due to speed variations (acceleration or oscillation), manufacturing inaccuracies, the rubbing of rolling elements against guiding race surfaces and cages, the displacement of the lubricant, and the rubbing of bearing seals.

According to Goodman's tests: the coefficient of friction of cylindrical roller bearings dropped from 0.0019 with increasing loads to 0.0013; in deep-groove ball bearings, the coefficient of friction first dropped from 0.0025 to 0.0014 with increasing load but upon further load increase it increased to 0.0020. Self-aligning ball bearings showed, with increasing load, first a drop from 0.0015 to 0.0011 and then an increase to 0.0014.

Muzzoli's tests indicate a steady decrease of the coefficient of friction with increasing load in cylindrical roller bearings without showing the reversal noticeable with ball bearing; the coefficient of friction is lower than that of ball bearings. They also show that deep-groove bearings with angular load have a greater friction increase with increasing angular loads than with radial loads alone and that angular-contact bearings have higher friction for

in the bearing axis perpendicular to the direction of load P_r are completely unloaded (see Fig. 7) and, in the axis coinciding with the load, are loaded approximately 50 percent higher than the individual uniform bearing load P_o of a bearing with a freely yielding outer race. Consequently, the specific radial load p_r is only about two-thirds of the specific axial load p_a or $p_r = P_r/D_iL \cong 0.65\eta_r k_o$.

In single-row ball bearings, D_iL becomes $D_i d_r$ and $\eta_r = nd_r/D_i\pi$ or $p_r \cong 0.65k_o nd_r/D_i\pi$. The radial load $P_r \cong fk_o n/5$ where f is the rectangle surrounding a rolling element $(= d_rL)$. This load is only one-fifth of the axial bearing load with the same number of balls.

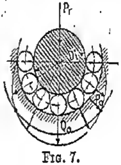

FIG. 7.

Stresses in Angular Bearings or Combination Radial-thrust Bearings. When radial bearings are used to support both axial and radial loads, an equivalent radial bearing load P may be used in place of P_r in the preceding formulas. The maximum ball load Q_o is given by the equation $Q_o = 5P_r/\eta \cos \alpha$. The value of P is given by

$$P = P_r + yP_a \qquad (3)$$

where y is a conversion factor and α the race contact pressure angle (Fig. 8).

The average y values for SKF bearings, according to the manufacturers, are as follows: for barrel-type roller-bearings, 2 to 3; for angular-contact ball-bearings, 0.33; for deep-groove bearings, 1 to 1.5; and for self-aligning ball-bearings, 1.5 to 4.5.

For single-row taper roller bearings, Timken gives the formula $P = 0.66P_r + kP_a$ where k averages 1.5 for standard bearings and 0.75 for steep-angle bearings intended for heavy thrust. If the calculated P is less than P_r, the thrust load P_a should be neglected and only the radial load P_r used.

Norma-Hoffman gives the following values for the equivalent bearing load P. With single-row deep-groove ball bearings when $P_a > \frac{1}{2}P_r$; $(P_a < \frac{1}{2}P_r)$; $[P_r = 0]$, the corresponding values of P are $0.5P_r + 1.5P_a$; (P_r); $[1.5P_a]$. With the single-row filling-notch type when $P_a > \frac{1}{3}P_r$; $(P_a < \frac{1}{3}P_r)$, the values of P are $\frac{1}{3}P_r + 2P_a$; (P_r). For double-row ball bearings, $P = P_r + 1.25P_a$. For angular-contact ball bearings, the equivalent thrust load is $2P_r + P_a$.

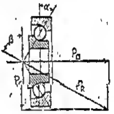

FIG. 8.

If a radial load P_r is imposed on an angular-contact bearing, it causes a thrust load P_a which necessitates an additional bearing on the same shaft. If α is the pressure angle (Fig. 8), $P_a = 1.22\,P_r \tan \alpha$ for ball bearings, $= 1.26P_r \tan \alpha$ for roller bearings (Juergensmeyer, *loc. cit.*).

Static Load Capacity

It is necessary to distinguish between static and dynamic load capacity. For the latter, see Relation of Load, Speed, and Bearing Life, p. 1036. The permissible static load upon a bearing is the non-brinelling static load, just before permanent surface deformation takes place. Exact experimental determination of this point is difficult; the first sign of brinelling can be noticed after reducing the bearing load and revolving it with an indicator against the races, a slight jump occurring when the rolling element travels over the brinelling mark. If the non-brinelling static load is exceeded with the bearing

equivalent to $0.625B_r \times 1422$ with a Brinell number $B_r = 667$ corresponding to an average race hardness of 63 Rockwell C.

The dynamic load capacity of the rollers is again substantially lower. For an average life of 2,500 hr, P_o the load rating becomes 4,580 lb at 100 rpm and 2,140 lb at 1,000 rpm, with k_o and p_m reduced accordingly.

Long Roller Bearing. A No. 1-7194 R.B.C. needle-roller-bearing with 29 rollers of 0.1205 in. diam and 0.700 in effective length, with 60–63 Rockwell C outer race and roller hardness and a shaft hardness of 60 Rockwell C, has a static non-brinelling load capacity of 1,625 lb per roller. The substitute radius d_r from formula (2) with an inner race (shaft) diameter of 1 in. is 0.1075 in. The static load factor $k_o = 1625/0.1075 \times 0.7 = 21{,}620$ lb per sq in. With $E = 30 \times 10^6$, $p_m^2 = 21{,}620 \times E/4.64$ and static $p_m = 374{,}000$ lb per sq in. This is equivalent to $0.42B_r \times 1422$ with a Brinell number B_r 627 corresponding to a shaft hardness of 60 Rockwell C.

The dynamic load capacity of the rollers is substantially lower, and according to the load ratings of the manufacturer for a 3,000 hr life, P_o becomes 905 lb at 100 rpm and 552 lb at 1,000 rpm.

Relation of Load, Speed, and Bearing Life

In correctly made, properly installed and lubricated bearings, the life is determined by fatigue of the material of races and rolling elements in contact with each other, and the time when fatigue failure occurs is dependent upon both the magnitude of the stresses and the actual number of stress applications.

Tests with many bearings conducted under carefully controlled conditions have provided the basis for the load ratings of the bearing manufacturers which are always based upon a certain life expectancy percentage.

No uniform practice has so far been established for the minimum life-expectancy percentages. SKF, Norma-Hoffman, Timken, Tyson, and Bantam, for instance, base their ratings on a minimum life expectancy of 90 percent of a large number of bearings tested under identical conditions with regular lubricant renewal.

The Hyatt ratings are based on a 50 percent average life expectancy of large numbers of bearings tested without any lubricant renewal.

The average life expectancy of a large group of bearings is 3½ to 5 times their minimum life expectancy. Some of the manufacturers ratings are based on average and some on minimum life expectancy.

According to the tests of the bearing manufacturers, the life of a radial or angular bearing may be expressed by

$$H = C/NP^x \tag{4}$$

where H is the number of hours of life, N the rpm, P the load (actual radial or equivalent radial load from formula (3)), C a constant depending upon the type and size of the bearing, and x an exponent which is given as 3 for *SKF*, 3.3 for Martin-Rockwell, and 3.33 for Tyson bearings.

If H_c is the average life of a bearing as rated by a manufacturer, and P_{av} the average total bearing load, lb, the expected actual bearing life H can be written as

$$H = H_cF^x \tag{5}$$

where F is the ratio of the catalogue load rating to P_{av}.

H_c is selected differently by the various manufacturers. SKF uses 2,500 hr. Bantam 3,000 hr, Fafnir and New Departure 3,500 hr, Martin Rockwell and Hyatt 5,000 hr, Norma-Hoffman 10,000 hr, average bearing life. Timken and Tyson ratings are based on 3,000 hr of minimum bearing life.

For a true comparison of bearing ratings, it is therefore essential to convert the catalogue ratings to the same average or minimum life expectancy.

PRINCIPAL STANDARD BEARING TYPES AND COMPARATIVE CHARACTERISTICS

Radial Ball Bearings

Fig. 13. Separable or magneto type, with ball separator.

Fig. 14*a*. Deep groove with uninterrupted raceways. Conrad type, built as single- and two-row bearings. With ball separator.

Fig. 14*b*. Deep groove with filling slots. More balls than Conrad type. Built as single- and two-row bearings with ball separator.

Angular Ball Bearings

Fig. 15*a*. Single-row type. With ball separator. Used also in pairs as duplex bearing.

Fig. 15*b*. Two-row type with filling slots for assembling. With ball separator.

Fig. 16. Two-row self-aligning type. With ball separator.

Radial Roller Bearings

Fig. 17. Roller bearings with short solid cylindrical rollers. Built with two lips on either raceway, three lips and four lips, also as full-type bearing without retainer but with retaining snap rings with and without inner race.

Fig. 18. Roller bearings with long solid cylindrical rollers of small diameter (needle roller bearings). No retainer. With and without inner race. Require ample diametral and very little circumferential play for satisfactory operation. Originally used for slow speed and oscillating parts, especially in limited spaces. Now also used successfully for certain higher speed applications such as Diesel engine connecting rod big end bearings, textile spindles, etc. Because of simultaneous rolling and sliding of the needles, ample lubricant circulation and, frequently, cooling are necessary for other than intermittent short runs.

Fig. 19. Roller bearings with short or long wound cylindrical rollers (Hyatt type). With retainers and solid or split outer races. With and without inner race.

Bearings with Tapered Rollers

Fig. 20*a*. With retainer. Race cones intersect in one point of bearing axis. Lip at large diameter of inner race takes up roller thrust and keeps rolls aligned. Lip intact either on spherical surface or in two points. Also built as two-row bearing with one inner race and two outer races or one outer and two inner races.

Fig. 20*b*. With snap ring. Full type. Four-point contact between extended inner race lip and roller end face.

Spherical Race Bearings

Fig. 21. Self-aligning bearing with two rows of short barrel rollers (SKF type). Spherical outer race in one piece or in two parts for preloading. Roller thrust taken on spherically shaped surfaces of center flange on inner race. Two-piece retainer.

Fig. 22. Self-aligning bearing with hourglass rollers (Shafer type). Spherical inner race. Retainer. Also built as two-row bearing with one piece inner race.

Axial or Thrust Ball Bearings

Fig. 23. Multirow flat race ball bearings with retainer. Also built as single-row bearing.

Fig. 24. Grooved-race single-direction ball bearings with retainer. Also built as self-contained type with and without ball retainer. Two direction bearings with three races and two rows of balls.

Fig. 25. Four-point contact single-direction bearings (Auburn type). Contact points of each race located in cone intersecting with similar cone of companion race in one point of bearing axis. Usually built as self-contained bearing without ball retainer. Two-direction bearings with three races and two rows of balls.

Roller Thrust Bearings

Fig. 26. Single direction. Bearings with cylindrical rollers. Short rollers stacked radially to reduce sliding. Thrust taken on retaining ring of separator. Two-direction bearings with three races and two sets of rollers.

Fig. 27. Bearings with tapered rollers. Race cones intersect in one joint of bearing axis. Roller thrust supported on lips of races and by separator. Also built as self-contained bearing without separator.

factors are based upon the service experience of the individual manufacturers of bearings who should be consulted regarding them.

Table 2. Corrections for Carrying Capacity of Bearings with Revolving Outer Races

Extra large, extra light	1.3				
Extra large, light	1.4				
Extra large, medium	1.5				

Clearance is the initial looseness of a self-contained bearing. Play is the possible total movement (axial, radial, or angular) of one race against the other when the bearing is subjected to load.

The play of installed bearings depends on bearing clearance, fit of the races, temperature difference of the races, elastic deformation of the races under load, the normal running accuracy of the mounted bearing, and the special characteristics of the type used. The first three factors are closely interrelated. Inner races expand when pressed onto shafts, thereby reducing the clearance. With extreme press fits, the race expansion may cause destructive loads upon races and rolling elements.

The bearing manufacturers have established practices for proper housing and shaft fits which should be closely adhered to, and where tight press fits are necessary it is possible to obtain bearings of appropriately greater clearance. For installations where play must be avoided, preloaded angular-contact bearings in pairs are available. To avoid excessive loads from race expansion, correct shaft and housing fits are particularly essential. Bearings with greater manufacturing tolerances or variations require more play than precision bearings so as to avoid mounting damage. Bearings without self-aligning features with sufficient play permit of slight misalignment or shaft deflection but the maximum stresses upon the rolling elements are increased.

Bearing Materials. Modern rolling-contact bearing races and rolling elements of better quality are generally made from high-carbon chrome-alloy steel, hardened throughout or surface hardened. S.A.E. steel 52100, heat-treated to a Rockwell C hardness varying from over 60 up 64, is very extensively used. These bearing steels corrode readily, and therefore only neutral lubricants should be used. For the same reason, the bearings must be protected against the intrusion of water, acids, alkalies, moisture, and active gases. Where liquids of this nature cannot be kept out, bearings can be supplied in a number of standard sizes from stainless steel. Such bearings are widely used in gasoline pumps and meters.

According to Norma-Hoffman, a heat-treated stainless steel of an approximate analysis of 0.95 to 1.05 carbon and 17.0–18.0 chromium can be hardened to as high as 60 Rockwell C hardness and over.

Separators for Rolling Elements. The purpose of separators or cages is to hold the rolling elements in proper relation to one race; to avoid contact between the rolling elements; to hold the rolling elements in place when one or both races are removed; to guide the rolling elements if there are no other means provided by the race tracks; and to dampen noise.

light axial load than deep-groove bearings but that the values approach each other with heavier loads.

Ball and cylindrical-short-roller bearings have low sliding friction because of small contact areas and high manufacturing accuracy. With [illegible] variations increase and shaft deflection and [illegible] to the increase in sliding friction.

Muzzoli's tests with needle bearings of 60 mm bore, 90 mm O.D., and 28 mm width with 79 needles of 3 mm diam and 19.8 mm long showed coefficients of friction ranging from 0.0083 under 440 lb load to 0.0044 under 46,400 lb load.

When sufficient space is available, oil-bath lubrication is preferable provided proper seals prevent oil leakage. For limited lubricant space, grease is preferable.

If the effect of seals is disregarded, which in properly designed installations can be entirely avoided, the friction of rolling contact bearing is not only very low, but also almost entirely independent of speed, load, and temperature; the starting friction is only very little higher than the running friction.

Under normal operating conditions, the temperature rise is slight, but at high speeds and with large bearings considerable heat is generated and oil circulation is necessary to carry off the heat.

BEARING STANDARDS

Various types of rolling contact bearings are now standardized as regards dimensions, in sizes ranging from fractions of an inch to 12 in. bore. The International and the major part of the S.A.E. standards for ball and roller bearings are based on metric dimensions. The S.A.E. standards for taper roller bearings are based on inch dimensions.

The regular radial and angular ball and roller bearing S.A.E. standard series are divided into light (200), medium (300), and heavy (400) series. The last one or two digits of the bearing number, beginning with digit 04, represent one-fifth of the bore in millimeters, and digits 00, 01, 02, and 03 represent 10, 12, 15, and 17 mm bore, respectively.

The wide metric ball and roller bearing S.A.E. series are also divided into light (5,200), medium (5,300), and heavy (5,400) series with the bore indicated in the same manner as in the regular series.

The S.A.E. standards covering one and two directions ball thrust bearings have not been generally adopted.

Ball and roller bearings of the same S.A.E. dimensions should not be used interchangeably in the same applications, because of different requirements for shaft and housing fits and, frequently, of different methods for holding the races in position. Taper roller bearings with standard bore and outside diameter require additional clearance space for projecting retainers.

In addition to the International and S.A.E. standard sizes, the bearing manufacturers have a great variety of other standardized sizes and types.

PACKINGS

BY

F. C. THORN

Packings include gaskets, valve disks and seats, sliding contact packings, and diaphragms.

Gaskets are installed between stationary surfaces, which consist of parallel flanges, or concentric cylinders. Flat gaskets for flange joints may extend beyond the bolts, as in (Fig. 1), but, since the portion beyond the bolt is of no value, the ring gasket (Fig. 2) is more economical. The materials used for flat flange gaskets, their compression characteristics, and service for which they are recommended are indicated in Table 1.

For greater compressibility than can be obtained with a flat gasket, a thick gasket, installed in a groove, may be employed. Unless the material is very hard, it is not good practice to permit the gasket to protrude from the groove (Fig. 3) since it is liable to "mushroom." Better practice is to employ a tongue-and-groove construction (Fig. 4).

In flange joints, the following rules should be observed:

1. Employ bolts of sufficient size and number so that, *after* deducting the relieving effect of internal pressure, the residual unit gasket load shall be 5 to 10 times the internal pressure.

Table 1

Type	Service principally	Common thickness, in.	Percent reduction in thickness at pressure[b]			Permenent set at 10,000 lb., percent
			500 lb	2000 lb	10,000 lb	
Sheet rubber	Water (low pressure)	1/16	8	14	37	10
Cloth-inserted sheet rubber	Water (low pressure)	1/16	4	7	33	16[c]
Corkboard	Oil (low pressure)	1/16	57	69	78	58
Gasket paper	Oil (low pressure)	1/16	13	22	31	14
Rubberized asbestos cloth	Hot water (boiler manholes, etc.)	1/4	11	22	34	31
Compressed asbestos sheet[a]	All services up to 600 F	1/16	1	10	16	6
Corrugated sheet-metal, with filling (Fig. 5)	Steam, oil at high temperatures	1/8	8	11	16	2
Metal jacket over asbestos center (Fig. 6)	Steam, oil at high temperatures, boilers, automobile cylinders, etc.	1/16	2	4	8	4
Spirally wound steel strip with intervening asbestos layers (Fig. 7)	Steam, oil at high temperatures, boilers	3/16	3	4	11	9

Solid metal, in flat, round, oval, or profile (Fig. 8) cross sections, is used with steam, oil, and gases at very high pressures and temperatures.

[a] Rubber compound containing about 70 percent asbestos fiber.

[b] Determined by cold compression of disks, 1 sq in. area by thickness indicated, except in case of semimetallic gaskets (Figs. 5, 6, 7) in which a $3\frac{1}{2} \times 4\frac{1}{2}$ in. gasket was tested (zero point in all cases taken at 7 lb per sq in. load).

[c] Fabric threads ruptured.

Compression is largely controlled by friction between platen and gasket. Smooth or lubricated platens, thicker or narrower gaskets, and, in most cases, higher temperatures give higher compressions at all loads. Set is increased by higher temperature and longer time under load.

Special-purpose Bearings

Fig. 28. Bearings with split tapered adapter sleeves. For use on straight shafts in any desired location. Also applied to deep-groove ball-bearing, and cylindrical short-roller bearings, usually with outer races having spherical seats. Extended solid inner races with setscrews or other locking devices are used for the same purpose.

Fig. 29. Snap ring bearings. Eliminate the necessity for machining housing shoulders to locate bearings. Also applied to needle bearings.

Fig. 30. Shielded bearings. Stamped disks attached to outer races assist in dirt protection and grease retention. Made with single- and two-row ball bearings. Used extensively as prelubricated types for inaccessible locations with lubricant sufficient for estimated bearing life.

Ball Bearings with Unground Races

Fig. 31. Grooved solid inner race with two-piece outer race held together by spun shell. Built in many modifications for radial, angular, and thrust loads of medium intensity and at moderate speeds.

2. Select a gasket wide enough to support, without crushing, the original bolt load *before* deducting for the internal pressure. Approximate values for crushing strength of gaskets at various thicknesses and temperatures can be obtained from the gasket manufacturer.

Most leaky joints are due to insufficient bolt pressure. If, however, the joint is designed to be self-tightening under pressure, as in the boiler manhole cover (Fig. 9), a single bolt in the center is sufficient.

Instances of gaskets packing concentric surfaces are the mechanical joint for cast-iron pipe (Fig. 10), the condenser tube-sheet ferrule (Fig. 11), and the ammonia condenser fitting. There are also gaskets shaped like cups and designed to be self-tightening under pressure, such as the gasket (Fig. 12) used with "boltless" autoclave doors.

Valve disks are specialized gaskets designed for joints that are frequently broken and restored. Disks for globe valves (Fig. 13) are usually encased in a disk holder with a swivel mounting, so that they do not rotate while closing. They are made of hard rubber or Bakelite. Hydrant valves (Fig. 14) are generally bevel-seated; they are made of medium hard rubber or leather. Pump valves (Fig. 15) are described on p. 1621. **Valve seats** of rubber are used with metal valve disks on some pumps, such as the *rotary drilling* pump (Fig. 16).

Sliding contact packings include all packings that operate against moving surfaces. A feature common to all of them is that they leak while in motion, although under favorable conditions the leak may be scarcely measurable and is frequently invisible if the fluid is a gas or becomes a gas on escaping. Leakage is increased by high pressures and low viscosity; it is minimized by deep packings and tight adjustment, but as both of these give rise to friction, it is not always possible to employ them, especially at high speeds. The only sure way to eliminate leakage is to inject into the packing another liquid at higher pressure, permitting it to leak both ways from the point of admission. This is the basis for the use of the **water seal** in centrifugal pumps (Fig. 27) and for the force-feed lubricating of metal packing sets (Fig. 24) when operating against steam or gases.

Sliding contact packings may be classified on the basis of the shape of the opposing surfaces—cylindrical, conical, spherical, or flat. Examples of the last three are, respectively, the plug-cock lining (Fig. 29), the ball-joint (Fig. 30), and the "rotary seal" when used in its restricted sense of a rotating collar operating against the flat end face of a stationary collar. Two types are shown: in the automobile water pump seal (Fig. 31), the rotating Bakelite sealing member is supported flexibly on a rubber cup; in the domestic refrigerator seal (Fig. 32), the stationary sealing member (bronze) is suspended by a diaphragm. Cylindrical packings may in turn be classified according to whether packing is accomplished on the outside perimeter, as in the piston packings (Figs. 17 to 20), or on the inside perimeter, as in the rod and shaft packings (Figs. 21 to 28). A second basis of classification is according to the type of motion—rotary, reciprocating, or helical (as in a rising stem valve packing). A third basis of classification is into automatic (*i.e.*, self-tightening under pressure) or non-automatic (*i.e.*, tightened by external means, generally a gland drawn into the opening of a stuffing box).

The simplest **piston packing** is the split ring (Fig. 17) constructed generally of cast iron and employed on pistons of gas, oil, and steam engines and compressors (see p. 848). Large pistons frequently employ segmental rings similar to metal rod packings (Fig. 24) but facing outward. These types are fully automatic, being driven against the cylinder wall by fluid pressure from within. Split rings made from layers of cotton fabric, bonded with rubber

E AND PIPE FITTINGS

BY

C. W. HAM

Piping Standards

Standardization in the piping industry has made rapid progress in recent years. In 1908, the A.W.W.A. adopted a set of specifications for cast-iron water pipe and fittings, largely replacing tho specifications adopted by the New England Water Works Association in 1902. Specifications for cast-iron gas pipe and fittings adopted by the American Gas Institute in 1913 were later revised and adopted by the American Gas Association. The A.S.A. has approved numerous standards for screwed and flanged fittings. In the pages that follow, the significant portions of many of these standards are given.

In June, 1935, the A.S.A., under the sponsorship of the A.S.M.E., issued The American Tentative Standard *Code for Pressure Piping* (A.S.A. B31.1-1935) covering steam, gas and air, oil, and district heating piping systems and fabrication details of pipe supports, bends, joints, valves, fittings, etc. The code recommends, or presents as mandatory, comprehensive applications of materials and products to the piping systems indicated above. It is intended to serve as a guide in the drafting of regulations and as a standard of reference for minimum safety requirements for those concerned with pressure piping. References to the code and brief abstracts will be given in the pages that follow. The code may be obtained from the A.S.M.E.

Cast-iron Pipe

Cast-iron pipe is extensively used for water, gas, sewage, culverts, drains, etc., in a wide range of sizes and for varying pressures, and is particularly **adapted to underground and submerged service** because of its comparatively high corrosion-resisting qualities. It is more durable than wooden-stave, wrought-iron, or steel pipe, but its first cost is greater for the ordinary sizes required in a pressure pipe line or in a distributing system. The tensile strength of commercial cast-iron pipe is uncertain, and, because of its low elasticity, it is not suitable for lines subject to the strains of expansion, contraction, and vibration, unless it is of very heavy weight. This pipe may be had in various thicknesses and weights with either **flanged ends** or **bell-and-spigot ends.** The latter are generally used for underground work, making a tight joint when properly put together, calked, and leaded. For exposed piping, flanged ends are used, the joints being made up with gaskets. Flanged pipe has superior strength and tightness of the joint and is used where pipe lines can be well supported. The bell-and-spigot joint possesses greater flexibility, provides for expansion and contraction, and is therefore especially suitable for water pipe and almost exclusively used for that purpose. Figure 1 shows the standard form of the joint for ordinary pressures. Other forms sometimes used in the United States are tho bell-and-plain-spigot and the turned-and-bored joints. Plain-end pipe with couplings for high-pressure gas mains and threaded pipe for corrosive liquids are also manufactured. Cast-iron pipe, fittings, and valves have not been found suitable for superheated steam service. The Code for Pressure Piping (A.S.A. B31.1-1935)

Fig. 1.

Comparative Features of the Principal Bearing Types

The criteria of Table 5 may be used for comparing the important characteristics of rolling contact bearings for the purpose of their appropriate selection.

Load Criterion (L.C.). Expressed in pound per square inch projected bearing area. The loads have been chosen arbitrarily, but with a view to a fair comparison of the load capacity of the different types. The principal manufacturers' load ratings at 300 rpm of bearings of the same inner race bore (or shaft diameter) have been converted into capacities for the same approximate minimum life expectancy of 3,000 hr and then divided by the projected bearing area (outside diameter minus bore times width). Averages from the calculated figures for bearings ½ to approx. 4 in. bore are used, unless otherwise stated. Either the radial L.C. or the axial L.C. are given and also the conversion factor X. (L.C. Radial) = X (L.C. Axial).

Shock Criterion (Sh. C.). The reciprocals of the recommended safety factors for shock as compared with a safety factor of 1 for steady load and speed conditions are used as criteria, bearings that require the largest shock safety factors therefore having the lowest relative shock resistance or criterion. The shock criteria are listed for US, uniform, steady load; MS, moderate shock; and ES, extreme and indeterminate shock.

Speed Criterion (Sp. C.). The average maximum rpm with rotating inner races of bearings having ½, 1, 2, and 4 in. bore of inner race (or shaft diameter) are used as criteria. For medium and heavy series S.A.E. dimension bearings, the bores of corresponding light series bearings with the same outside diameter apply.

Friction Criterion (Fr. C.). The relative magnitude are expressed as L (low), ML (medium low), M (medium), MH (medium high), H (high).

Acoustic Criterion (A.C.). The relative bearing noise is expressed by S (silent), FS (fairly silent), and N (noisy) at speeds from approximately ⅛ to ½ the maximum bearing rpm up to maximum bearing rpm.

Misalignment Criterion (M.C.). Expressed by internal ability to compensate for misalignment and shaft deflection. EM is extreme misalignment (±5 percent); SM, slight misalignment (±1 percent); and NM, no misalignment.

Axial Location Criterion (A.L.C.). Expressed by the number of bearings (1 or 2) needed to stabilize a shaft assembly axially.

Mounting and Maintenance of Rolling Contact Bearings

It is essential to protect rolling contact bearings from the effects of dirt, grit, and splash by suitable seals, which should also prevent lubricant leakage. Grease is used with limited axial space, in poorly accessible locations, and in prelubricated bearings. The principal seals used are felt, leather, and cork (usually for liquid-splashed or submerged bearing installations); and labyrinth seals, alone or in combination, with other seals. For high speed applications labyrinth seals only should be used. Where oil bath lubrication is employed, there should be ample axial space for the displaced lubricant in rotation without churning.

The most important advantage of rolling contact bearings over plain bearings is their availability as complete units, standardized over a wide range of sizes, and with definitely known load characteristics. In addition, they are largely free from leakage of lubricant, have low starting friction, can be operated at great speeds, require little repair, and cover any desired life expectancy. Lubrication is necessary only at long intervals.

The disadvantages are higher first cost, the impossibility of quick or temporary repairs, the more complicated shaft and housing design, greater noise (especially at high speeds), lower resistance to shock, general nonavailability as completely split types, substantially larger bearing diameters except with certain types of needle bearings, and the serious effects of dirt and grit.

states that cast iron shall not be used for any service over 450 F and not for oil over 300 F.

The **specifications** of the A.W.W.A. for bell-and-spigot pipe are now used generally as the manufacturers' standard throughout the United States. Standard dimensions are given in Tables 1 and 2. Brackett's formula for the thickness of cast-iron pipe is $T = 0.25 + (P + P')r/3,300$, in which T is the thickness, in.; P the maximum static pressure, lb per sq in., for which the pipe is designed; P' the allowance made for water ram; and r the radius, in. This gives a large factor of safety to cover inequalities of the castings, strains brought on the pipe from other causes than the water pressure, and to give sufficient thickness to ensure the pipe against breakage in shipping and laying. For ordinary waterworks conditions for pipes, 42 to 60 in. diam, 70 lb per sq in. is enough for P', but for smaller pipe Brackett allows the following values:

Diam of pipe, in.	= 36	30	24	20	16	12	10 to 3
P', lb per sq in.	= 75	80	85	90	100	110	120

Table 3. Weight of Lead Required for Cast-iron Bell-and-spigot Pipe

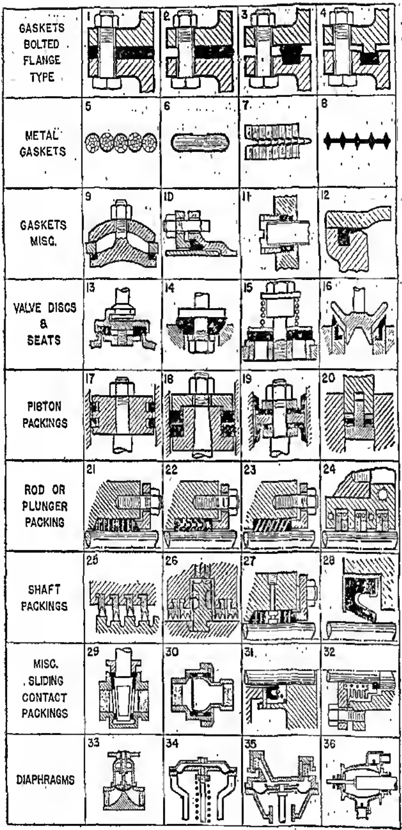
Depth of joint, in.	Diameter of pipe, in.															
	4	6	8	10	12	14	16	18	20	24	30	36	42	48	54	60
	Approximate weight of lead per joint, lb															
2	8	10	13	16	19	22	30	34	37	44	54	65	75	86	98	108
2½	9	12	16	19	23	26	36	40	44	53	65	77	86	102	117	130
Solid	13	18	23	31	37	39	65	72	80	95	118	140	155	202	239	256

For city work where great damage would be caused by breakage, and for single lines with no reserve, where an interruption of the supply would be a very serious matter, the pipes may be made thicker than computed by this formula. See the A.S.A. proposed new method of determining thickness.

The employment of **cast-iron pipe for** gas supply and distribution is second in importance only to its use for carrying water. In this country the bell-and-spigot type of joint, similar to that for water (Fig. 1) has generally been found to meet all requirements for gas. Abroad, however, practice varies and the turned and bored joint is preferred by many prominent users. Standard bell-and-spigot gas pipe has dimensions and weights approximately the same as water pipe of Class A, Table 1. Standard heavy gas pipe has dimensions and weights similarly approximating Class B, Table 1. Standard flanged gas pipe has dimensions and weights approximately the same as flanged water pipe of Class A, Table 5.

The **specifications** of the American Gas Association are the generally accepted standards for cast-iron gas pipe and fittings. These specifications are based largely on those of the A.W.W.A. (see above). While the flange diameters, bolt circles, etc., of the American Standards for steam (see p. 922) have been generally adopted by the manufacturers of flanged pipe for water, the standards of the American Gas Association are used for flanged gas pipe.

Pipe Joints. The most common method of making the bell-and-spigot pipe joint is by pouring and calking the lead into the bell. In the built-up sections of cities, where streets are crowded underground with other structures, and surface traffic is heavy, the tendency seems to be to increase the thickness of metal, and to use exclusively (even for gas) pipe having bells calked with lead, as securing the most flexible joint. Such pipe with lead joints are also preferable where conditions of subsoil, as in newly made ground, indicate a possible subsidence. One advantage of a lead joint is that if it leaks, simple recalking will usually correct the trouble, whereas a cement joint must



FIGS. 1-36.—Packings.

iron joint. By making the tapers of slightly different pitch, the joint provides *for flexibility while remaining tight.* Two bolts to the joint are sufficient, except for pressures above 175 lb per sq in. "Universal" cast-iron pipe is largely used for carrying gas and water and is suitable for all pressures and services. The pipe is tested with hydrostatic pressure of 300 to 500 lb per sq in. All universal pipe and special castings of a given diameter and of any class are interchangeable with those of a different class. Standard laying lengths, 6 ft. Thicknesses and weights are given in Table 7.

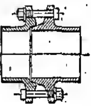


FIG. 4.—"Universal" C. I. Pipe.

Fittings for Cast-iron Water Pipe. Flanged fittings *of the dimensions of the American Standard for steam are* not often used with cast-iron water pipe. The longer fittings of the A.W.W.A. are generally preferred because of lower friction loss. The dimensions of the flanged fittings of this class conform very closely to the dimensions of the bell-and-spigot fittings of the *A.W.W.A. The flange thicknesses conform to those of the American Standard* (see pp. 923 and 924) and they are drilled to American Standard templates. These fittings, both flange and bell-and-spigot type, are made in a great variety of forms known as "Standard Special Fittings." For dimensions and weights, see manufacturers' catalogues, or standard specifications of the A.W.W.A.

* Flange dimensions and drilling conform to "American 125 lb Standard" (see Table 27, page 923). Thicknesses conform to those of the A.W.W.A. (see Table 1).

Cast-iron soil pipe and fittings are of the hub and spigot form, similar in design to the cast-iron water pipe shown in Fig. 1. Tapped openings and pipe plugs are threaded in accordance with the American Standard taper pipe thread, A.S.A.-B2.

or Bakelite, are employed for water pumps, gasoline pumps, etc., and are sometimes arranged so that they can be tightened by a gland as in (Fig. 18). Cups are fully automatic and are very tight; they are used principally for slow-speed applications, such as the air hoist (Fig. 19). See also p. 852. The Bridgman piston (Fig. 20) is a modification of the conventional piston designed to be self-tightening under pressure; it has been used for high-pressure gas experiments and employs a rubber ring.

The end rings used in the square **rod or plunger packing** (Fig. 21) are generally molded to an angle of 30 deg to the vertical, either in manufacture or by contact with the gland and bottom of the box. Many materials are employed, such as leather or braided flax saturated with wax for cold water; laminated rubberized-cotton fabric for hot water, low-pressure steam, ammonia, etc.; rolled rubberized-asbestos fabric for steam and air; and rolled or twisted metal foil for high temperature and high pressure conditions generally. The nested V and nested conical packings (Figs. 22 and 23) are semiautomatic and generally superior in performance to the square rings—they are made from the same materials and used for the same services. The floating metal rings (Fig. 24) are made of numerous radial or tangential segments to enable them to contract on the shaft; they are assembled generally in pairs to break joints, and with garter springs to hold them together. They are used for steam, gas, or air under the most severe conditions of temperature and pressure, and are supplied with lubricating oil. For general stuffing box design see p. 853; for pipe expansion joints, p. 940.

Among the rotary **shaft packings**, the **labyrinth** packing (Fig. 25) differs from all the preceding in that no attempt is made to hold to close clearances; leakage being controlled by forcing the escaping fluid to travel in a circuitous path (see p. 852 and 1198). The liquid seal (Fig. 26) likewise does not operate on close clearances; it depends on the principle of the U tube, the natural weight of the liquid in the example shown being magnified by centrifugal force. Both these are used for steam turbines (see p. 1200). Square packings as well as the nested-V and conical types are also largely employed for rotary shafts. Where it is desired to effect complete sealing, as on centrifugal pumps, it is common practice to inject water or other fluid into the packing by way of the H-shaped **lantern ring** shown in Fig. 27. Square packings for rotary shafts are made, in general, of the same materials as the corresponding reciprocating packings, braided asbestos yarn with a binder of grease and graphite being perhaps the most popular type, for both centrifugal pump and valve-stem applications. **Plastic packings** consisting of loose mixtures of asbestos fiber, graphite, metal, and a binder are being used to an increasing extent.

Cups with an inside lip, sometimes known as **hat packings**, are widely used as oil-retaining rings on rotary shafts. They are of leather or rubber composition (Fig. 28) and are provided generally with an internal spring and a metal case which is pressed into a corresponding cavity surrounding the shaft.

Diaphragms are used for the same purposes as sliding contact packings and are entirely leakless, although somewhat limited as to travel. The use of the cylindrical metal diaphragm (bellows) as a rotary seal suspension is shown in (Fig. 32). In the diaphragm valve (Fig. 33) the diaphragm replaces both the conventional stem packing and valve disk. Diaphragms of rubberized-cotton fabric are used in pumps (Fig. 35) and in motors (Fig. 34) to operate valves and switches. When correctly designed, they are made with slack to permit a natural rolling motion. The rubber diaphragm in the Abercrombie pump (Fig. 36) is unusual in that the diaphragm is under fluid pressure on both sides and is therefore unstressed.

sure gas mains. It is also concentric in section and of uniform thickness. For list of sizes, types of joints used, etc., refer to general catalogue of U. S. Cast Iron Pipe and Foundry Co.

[a] Tapped up to 2 in.
[b] Weights of pipe include the hub. Laying lengths of pipe are 5 ft. From the data given for staple fittings, weights of other fittings may be estimated. For data on pipe *sizes 8, 10, and 15 in. and other data, see A.S.A. A40.1-1935.*

Steel Pipe and Tubing

Designation of Pipe Size. Commercial sizes of wrought-iron and steel *pipes and tubes are known by their nominal inside diameter from ⅛ to 12 in.* Above 12 in. diam, pipes and tubes are usually known by their outside diameters (O.D.). The outside diameter of all classes of pipe and tubing heavier than standard is the same outside diameter as standard, the extra thickness always being on the inside.

In ordering pipe 12 in. and smaller designate weight desired, and in ordering tubes designate thickness desired.

Standard pipe (Table 9) is furnished in sizes ⅛ to 12 in., in random lengths, threaded both ends, with coupling on one end. The length measurement is from end to end including coupling. **Extra strong pipe** (Table 10) is heavy pipe used for high steam, gas, and hydraulic pressures. Sizes are ⅛ to 12 in., and random lengths 12 to 22 ft. **Double extra strong pipe** (Table 11) is suitable for very high pressures. Sizes are ½ to 12 in., and random lengths 12 to 22 ft. **Outside diameter pipe** runs in sizes from 14 in. up. Extra strong, double extra strong, and outside diameter pipe are furnished with plain ends and in random lengths unless otherwise specified.

American Standard Wrought-iron and Wrought-steel Pipe

(A.S.A. B36.10-1939)

The dimensional standarde for pipe are based on products such as are covered by the A.S.T.M. and A.S.A. specifications of Table 12. Nominal wall thicknesses are given in Tables 13 and 14 for steel and wrought-iron pipe, respectively. *Actual wall thicknesses should not be more than 12½ percent below the nominal wall thicknesses of the tables.* Screw threads of threaded pipe and couplings should conform to the American Standard A.S.A. B2 (Table 11) or, for threaded line pipe as used in the petroleum and gas industries, to A.P.I. 5-L.

Recommended values of S (see "Thickness of Pipe," below) are given in Table 10. The user should compute the exact value of wall thickness for his conditions as described below and then select a thickness from Tables 13 and 14.

Line Pipe Specifications (A.P.I. 5-L), tensile strength, min, lb per sq in. **Furnace welded:** Bessemer, 50,000; O.H.; Class I, 45,000; Class II, 48,000: wrought iron, 42,000. **Seamless or electric welded:** O.H.; Grade A, 48,000; Grade B, 60,000; Grade C, 75,000. **Seamless or furnace welded:** O.H., iron, 42,000. **Seamless carbon-molybdenum alloy steel pipe** (A.S.T.M. A206-38T): 55,000 lb per sq in., for temperatures 750 to 1000 F. **Seamless alloy-steel pipe** (A.S.T.M. A158-38T): 60,000 to 75,000 lb per sq in., for temperatures 750 to 1100 F. Scope: Pipe for line pipe purposes, to convey gas, water, or oil. Sizes covered, ⅛ in. nominal size to 24 in. outside diam. *Couplings for threaded line pipe are of special design.* Threads on pipe and in couplings are subject to official gage limits.

Thickness of Pipe. *The following notes, covering power piping systems,* have been abstracted from Section I of the Code for Pressure Piping (A.S.A. B31.1).

For inspection purposes, the minimum thickness of pipe wall to be used for piping at different pressures and for temperatures not exceeding those for the various materials given in Table 16 shall be determined by the formula:

$$t_m = (PD/2S) + C$$

where t_m = minimum pipe wall thickness, in. allowable on inspection; P = maximum internal service pressure, lb per sq in. gage (plus water hammer allowance in case of cast-iron pipe conveying liquids); D = outside

be entirely cut out and remade, and the dirt and old cement adhering to the pipe are likely to interfere with the perfect bonding of the new joint. Cement joints for gas pipe are fairly common practice, and, to a smaller extent, for water pipe.

Cast-iron pipe should be made of a soft and tough quality of iron and should be subjected to a test pressure of at least twice the working pressure. A good grade of cast iron shows the following properties: tensile strength, 20,000 lb per sq in.; a test bar 1 × 2 in. in section should support a central load of 2,000 lb when placed flatwise on supports 24 in. apart; if loaded to breaking, it should show a deflection of not less than 0.30 in. before fracture. Cast-iron pipe is coated by dipping in hot coal-tar pitch varnish before being laid in the ground.

Flexible Joint Pipe. The necessity for crossing streams and other waterways and of laying pipe lines into them has developed various forms of flexible joint pipe adapted to laying under water, which, when calked with lead, are capable of motion through several degrees without leakage. Figures 2 and 3 show two styles of such joints which have an adjustment of 10 to 12 deg in standard sizes. The lead flexible joint (Fig. 2) is the one generally used. Figure 3 shows a more expensive joint intended for use in swift water where there is danger of pulling apart; it can be calked before shipment.

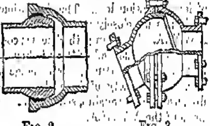

Fig. 2. Fig. 3.
Flexible Pipe Joints.

In selecting the thickness of a pipe for a submerged line, the internal service pressure is seldom the determining factor, as ample allowance should be made to minimize the risk of breakage in laying and to withstand external shocks from floating ice or other objects. The thicknesses and weights given in Table 4 are in accord with good practice.

Table 4. Thicknesses and Weights of Flexible Joint Pipe*

Nominal diam, in	Class	Thickness, in	Weight per 12-ft length, lb	Lead per joint, lb	Nominal diam, in	Class	Thickness, in	Weight per 12-ft length, lb	Lead per joint, lb

The schedule numbers are approximate values of 1000P/S (see p. 908 for the symbols). Thicknesses include a mill tolerance of 12.5 percent. Thicknesses in black type in schedules 30 and 40 agree with those of standard weight pipe, Table 9; those in schedules 60 and 80 with extra strong pipe, Table 10.

DeLavaud Centrifugally Cast Cast-iron Pipe. The utilization of centrifugal force in the manufacture of cast-iron pipe has developed a method that produces pipe superior in many respects to that cast in sand molds. A metal mold is rotated horizontally as the molten metal is fed into the mold so that the rotary force throws the metal against the mold, forming the pipe. This process forces from the metal the impurities and gives it a very homogeneous structure. The outstanding feature of this pipe is the great increase in strength resulting from the process. Being free from blow holes and impurities and of closer grain than sand-cast pipe, it is of particular value for high-pres-

Cast-iron pipe, centrifugally cast[d]	F.S.B. WW-P-421	.....	6,000				
Cast-iron pipe, pit-cast[d]	A.W.W.A	.....	4,000				

To the minimum pipe wall thickness calculated from any of the above S values, the manufacturing tolerance, demanded for the pipe considered, must be added to obtain the nominal wall thickness. (See A.S.A.-B36.)

[a] Pipe in accordance with A.P.I. specification 5L may be used.

[b] The several types and grades of pipe tabulated above shall not be used at temperatures in excess of the maximum temperatures for which the S values are indicated. If it is desirable to use an adjusted value of S for carbon-steel pipe at temperatures below 700 F., the curve of Fig. 5 may be utilized.

[c] If plate material having physical properties other than stated in Section 6 of A.S.T.M. specification A139 is used in the manufacture of ordinary electric-fusion-welded steel pipe, the allowable stress shall be taken as 0.15 times the tensile strength for temperatures above 700 F but not over 750 F, and 0.16 times the tensile strength for temperatures of 700 F and below.

[d] Cast-iron pipe shall not be used for lubricating oil lines for mechinery and in any case not for oil having a temperature above 300 F.

TS = ultimate tensile strength of the material.

E = efficiency of the joint.

low-carbon seamless steel (A53) or wrought iron (A72) are suitable. Pipe permissible for this service may be used for temperatures above 450 F if the proper S is used in calculating the pipe-wall thickness.

Valves below 3 in. may have inside stem screws. Stop valves 8 in. and over must be by-passed. Bodies, bonnets, and yokes shall be of cast iron, malleable iron, steel, bronze, brass, or monel. Flanged-steel fittings must conform to the 300 lb American Standard B16e; if of cast iron, to the 250 lb American Standard B16b or for screwed fittings, B16d. Malleable-iron screwed fittings shall conform to the 300 lb M.S.S. SP-31, except that the 150 lb American Standard B16c may be used for pressures not greater than 150 lb. Welded fittings may be used.

Steam Pressures from 25 to 125 Lb, Temperature Not above 450 F. Pipe may be of steel, wrought iron, cast iron, copper or brass; valve bodies of cast iron, malleable iron, steel or brass. Fittings shall be of 125 lb American Standard with screwed (B16d), flanged (B16a), or malleable-iron screwed fittings (B16c).

Steam Pressures 25 Lb and less, Temperatures up to 450 F. Pipe may be of steel, wrought iron, spiral riveted steel, brass, copper, or cast iron. Flanged fittings shall conform to the 25 lb American Standard B16b2. Screwed fittings shall be of the 125 lb American Standard B16d or of the 150 lb American Standard B16c for cast iron or malleable iron, respectively, or the M.S.S. SP-10 for bronze. Welded fittings may be used.

Table 17. Capacity of Pipes and Cylindrical Tanks of Various Diameters in Gallons per Foot of Length

(For capacities in cubic feet, use table of areas, p. 33)

Pipe Bends. For theory and design, see p. 497. Pipe bends of any size and shape can be obtained to suit almost any condition arising in practice. Various shapes of pipe bends are shown in Fig. 6, some limiting dimensions of which are given in Table 18. Their uses may be broadly classed as follows: (1) For steam lines to provide flexibility and compensate for expansion and contraction; (2) to reduce the number of joints in a pipe line; (3) to avoid obstructions such as columns, pipe foundations, which otherwise would require several pieces of pipe and fittings; (4) to reduce friction in piping; (5) for coils in heaters, refrigerating systems, etc.

diam of pipe, in.; S = allowable stress in material, lb per sq in.; C = allowance for threading, mechanical strength, and corrosion, in.

Values of S for various materials and temperatures contemplated shall not exceed those given in Table 16. (Continued on p. 911.)

Table 12. A.S.A. Specifications for Tensile Strength of Pipe

A.S.A. designation	A.S.T.M. designation	Style of pipe	Tensile strength, min, lb per sq in.	Scope
B36.1	A53	Welded and seamless steel	Welded: Bessemer, 50,000; O.H. 45,000. Seamless: low carbon, 48,000; medium 62,000	(a)
B36.2	A72	Welded wrought iron	40,000	(b)
B36.3	A106	Lap-welded and seamless steel for high temperatures	Welded: O.H. 45,000. Seamless: Grade A, 48,000; Grade B, 62,000; Grade C, 75,000	(c)
B36.4	A134	Electric-fusion-welded steel, sizes 30 in. and over	See A.S.T.M. Standard A134	(d)
B36.5	A135	Electric-resistance-welded steel	Grade A, 48,000. Grade B, 60,000	(e)
B36.6	A136	Forge-welded steel	Grade A, 45,000. Grade B, 50,000	(f)
B36.7	A137	Lock-bar steel	Plates: 55,000 to 65,000. Lock-bars; 40,000 to 50,000	(g)
B36.8	A138	Riveted steel and wrought iron	Plates: Steel, 55,000 to 65,000; wrought iron, Class A, 48,000; Class B, 47,000 Rivet bar stock; steel, 45,000 to 55,000; wrought iron, 47,000	(h)
B36.9	A139	*Electric-fusion-welded* steel, 8 to 30 in.	*Grade A, 48,000. Grade B, 60,000* or other material	(i)
B36.11	A155-36	Electric-fusion-welded steel pipe for high-temperature high-pressure service	Grade A, 45,000; Grade B, 50,000; Grade C, 55,000	(j)
G8.7	A120	Black and hot-dipped galvanized welded and seamless steel	Same as B36.1	(k)

(a) Commercial steel pipe for general uses, also for coiling, bending, flanging, and similar forming operations when so specified.

(b) Commercial wrought-iron pipe for general uses, also for coiling, bending, flanging, and other special purposes.

(c) Lap-welded and seamless steel pipe for high-temperature service. Suitable for bending, flanging, and similar forming operations.

(d) Covers pipe 30 in. diam and over in wall thicknesses up to ¾ in., fabricated from steel plates by electric-fusion welding.

(e) Pipe up to 30 in. intended for conveying liquids, gas, or vapor at temperatures below 450 F. Adapted for flanging, bending, and similar forming operations in Grade A class.

(f) Covers sizes 14 to 96 in., wall thicknesses ¼ to 1¼ in., forge welded from steel plates and intended for various uses.

(g) Covers sizes 20 to 72 in., wall thicknesses $\frac{3}{16}$ to ½ in., fabricated from plates with H-shaped lock bars for the longitudinal seams. Suitable for conveying liquids or gases.

(h) Shop-fabricated pipe suitable for conveying liquids or gases; made from steel or wrought-iron plates with riveted seams.

(i) Covers sizes *8 to <30 in.* in wall thicknesses not over ⅝ in., fabricated from steel plates by electric-fusion welding. Intended for conveying liquids, gas, or vapor at temperatures below 450 F. Adapted for flanging and bending.

(j) Electric-fusion-welded steel pipe having an outside diameter of 18 in. and over for high-temperature and high-pressure service. Suitable for bending, flanging, corrugating, and similar forming operations. Welding in accordance with Par. U-68 of the A.S.M.E. code for unfired pressure vessels.

(k) Commercial steel pipe for ordinary uses such as low-pressure steam, liquid, or gas lines. Not intended for coiling or close bending, nor for high-temperature service.

The radii of pipe bends and lengths of tangents should preferably equal or exceed the minimum values given in Table 18. Bends with plain or beveled ends, for welding, can be furnished without tangents, but for convenience in erection it is recommended that they have tangents at least equal to the minimum lengths given in Table 18 for threaded ends. Bends with slip-on flanges can be furnished with a minimum length of tangent equal to the length through the hub of the flange. Those fitted with welding neck flanges can be furnished without tangents. When possible, however, the use of a tangent is recommended for convenience in erection.

Table 18. Limiting Dimensions of Pipe Bends
(Letters and dimensions refer to Fig. 6. All dimensions are in inches)
(From Crane Co. catalogue)

Size of pipe, in.[a]	Minimum recommended radius[b] R	Shortest radius, in., to which pipe can be bent								Minimum length of tangent, in.[b] X	
		Steel pipe				Wrought-iron pipe					
		Threaded ends, screwed, or welded flanges		Lap joints		Threaded ends, screwed, or welded flanges		Lap joints

12	60	46	36	46	36	46	42	46	42	14	10
14 O.D.	70	60	48	60	48	60	54	60	54	16	14
16 O.D.	95	80	60	80	60	80	70	80	70	18	16
18 O.D.	108	90	66	90	66	90	80	90	80	18	18
20 O.D.	120	100	72	100	72	100	90	100	90	18	18
24 O.D.	144	144	108	144	108	144	122	144	122	18	20

[a] For sizes 14 in. O.D. and larger, radii under standard pipe are based on a wall thickness of $\frac{3}{16}$ in. or less. The radii under extra-strong pipe are based on a wall thickness of ½ in. or greater.
[b] For steel or genuine wrought-iron pipe, in "standard" or "extra-strong" weight.

Pipe coils are made from any of the commercial sizes of iron, steel, brass, and copper pipe and tubing. Limiting center to center dimensions to which pipe coils can be fabricated in sizes ¼ to 2 in. according to the recommenda-

The permissible variation *in* weight *for any length of pipe is 10* percent above and 3½ percent below; but the carload weight shall not be more than 1¾ percent under the nominal weight.

Furnished with threads and couplings and in random lengths, unless otherwise ordered.

The weight per ft of pipe with threads and couplings is based on a length of 20 ft, including the coupling.

Lap-weld not furnished in sizes below 1½ in.

The value of C shall not be less than the following:

Type of pipe	Value of C, in.
Cast-iron pipe, centrifugally cast or cast horizontally in green sand molds	0.14
Cast-iron pipe, pit cast	0.18
Threaded steel, *wrought-iron or non-ferrous pipe* (n = number of threads per in.)	$0.8/n$
Grooved steel, wrought-iron or non-ferrous pipe	Depth of groove
Plain end steel, wrought-iron or non-ferrous pipe or tube for 1 in. size and smaller	0.05
Plain end steel, wrought-iron or non-ferrous pipe or tube for sizes above 1 in.	0.065

(Continued on p. 913.)

tion of Crane Co. are given in Table 19. Steel tubing cannot be bent to the absolute limits of brass or copper.

Tubular Products. The following material from the catalogue of the National Tube Co. covers tubular products such as boiler tubes; steel tubes; oil-well pipe, casing, and tubing; signal pipe; trolley poles; cylinders and shipping containers; seamless mechanical tubing; aircraft tubing; tubular forgings; etc.

These products are made by either of two basic processes, welded or seamless. Welded products are made in sizes $\frac{1}{8}$ to 96 in. diam and, in certain sizes, in lengths up to 40 ft. Seamless products are made in sizes from $\frac{1}{8}$ to 28 in. and, in certain sizes, in lengths up to 45 ft. Three processes are used in making welded products: butt weld in sizes $\frac{1}{8}$ to 3 in.; lap weld in sizes 2 to 24 in.; and electric weld in sizes 30 to 96 in. Seamless products are also made by three processes: piercing in sizes up to 14 in.; rotary rolling in sizes 14 to 28 in.; and cupping in sizes $5\frac{1}{2}$ to 30 in.

NOTE. In estimating effective steam-heating or evaporating surface of tubes, the surface in contact with air or gases of combustion, according to manner of application, as whether internal or external, is to be thus taken. For heating liquids by steam, superheating steam, or transferring heat from one liquid or one gas to another, mean surface of tubes to be computed.

The steels used for tubular products conform to standard specifications. For example, the A.P.I. specification 5A gives tensile strengths as follows: seamless steel, Grades *A*, *B*, *C*, and *D*, 48,000, 70,000, 75,000, and 95,000 lb per sq. in., respectively; open-hearth welded steel, classes I and II, 45,000 and 48,000 lb per sq in., respectively; Bessemer welded steel, 50,000 lb per sq in.

Seamless mechanical tubing is available in a wide range of diameters and wall thicknesses. Diameters of round tubing range from $\frac{1}{8}$ to 20 in. outside diameter and wall thicknesses from 20 gage (B.W.G.) to 2 in. Oval, square, and rectangular shapes are also available. Round tubing is listed in a range

Plain end pipe includes pipe joined by flared compression couplings, lapped joints, and by welding, *i.e.*, by any method that does not reduce the wall thickness of the pipe at the joint.

Water-hammer allowance for cast-iron pipe to be added to P in the formula is as follows:

Pipe size, in.	4–10	12–18	20	24–30	36–48	54–84
Water-hammer allowance, per sq in.	120	110	100	95	90	85

Having computed the exact nominal thickness, as outlined above, a schedule number may be selected from Tables 13 or 14 the thickness of which is not less than the computed value.

For pressure-temperature ratings of carbon-steel pipe at temperatures below 700 F, Fig. 5 may be used. For higher temperatures, the S values in Table 16 apply.

Physical and Chemical Properties of Pipes, Tubes, Etc. The design of piping for operation above 850 F presents many problems not encountered at lower temperatures. For the properties of steel applicable to high-temperature service (as well as to ordinary service) for pipes, tubes, fittings, bolting material, etc., see p. 571. For a discussion of creep properties, see p. 428. See also recent publications of the National Tube Co.

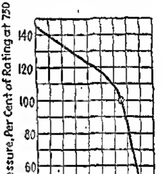

FIG. 5.—Pressure-temperature Rating Chart for Carbon-steel Pipe.

A.S.A. Code for Steam Piping

(A.S.A. B31.1-1935)

Quantities in parentheses are A.S.T.M. Specification numbers.

Steam Pressures from 250 to 1,500 Lb, Temperatures 450 to 750 F. For pressures in excess of 400 lb per sq in., the pipe may be seamless steel (A106) or, for high-pressure, high-temperature service, electric-fusion-welded steel (A155). For pressures between 250 and 400 lb per sq in., the pipe may be lapwelded or seamless steel (A106), or, for high-pressure, high-temperature service, electric-fusion-welded steel (A155), electric-resistance-welded steel (A135), or seamless steel (A53). For pressures not greater than 250 lb per sq in., the pipe may be electric-fusion-welded steel (A134 or A139), forge-welded steel (A136), welded steel (A53), or wrought iron (A72). For close coiling or cold bending, the pipe may be low-carbon or Grade A seamless steel (A155 and A156), wrought iron (A72), or Grade A electric-welded pipe (A135 or A139). When the temperature is higher than 750 F, unless otherwise prohibited, the proper S value may be obtained from Fig. 5.

Valves and fittings must have flange openings or welded ends and valves must have external stem threads. Valves must be of cast or forged steel or of forged or cast non-ferrous material. Malleable iron may be used up to 300 lb pressure and 500 F. For 3 (2) [1½] in. pipe and pressure from 250 to 400 (400 to 600) [600 to 1500] lb, forged and cast-steel screwed valves and fittings may be substituted. Malleable-iron screwed fittings (300 lb M.S.S. SP-31) may be used for pressures not greater than 300 lb and temperatures not over 500 F. Valves 8 in. and larger should have the by-pass of at least ¾ in., commercial size. Welded fittings may be used of the same material and thickness as the pipe with which they are to be used.

Steam Pressures from 125 to 250 Lb, Temperature Not Above 450 F. Pipe may be electric-fusion-welded steel (A134 or A139), forge-welded steel (A136), welded steel (A53), or wrought iron (A72). Copper and brass may be used if the temperature does not exceed 406 F. Cast iron may also be used. For close coiling or cold bending,

The sleeve-type coupling illustrated in Fig. 7 is particularly suitable for plain end pipe and is widely used. A gasket is used to make a tight joint. Advantages of this coupling are low cost, the use of unskilled labor in making the connections, and the fact that small changes in alignment and grade can be made with regular, straight lengths of pipe by a movement in the coupling. This type of coupling is used extensively in long oil lines, on high-pressure natural gas lines, and on water lines.

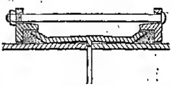

Fig. 7.—Sleeve-type Plain-end Coupling.

Pipes and Tubes of Copper, Brass, Lead, Tin, and Aluminum

Brass and copper tubes are listed by the manufacturers in even outside diameters and in wall thicknesses conforming to Stubs gage. **Brass and copper pipe** are available in "standard" and "extra-heavy" iron pipe sizes (Table 23). To obtain the approximate weight per foot of brass and copper pipe or tubes, use the following densities: yellow brass, 0.307 lb per cu in.; copper, 0.323 lb per cu in.

Table 23. Weight of Yellow Brass and Copper Pipe

From tests on pipe bends made by Crane Co. (*Valve World*, Oct., 1915), the following facts were established:

1. Extra-strong pipe bends have practically the same expansion value as the corresponding shape full-weight pipe bends.

2. The tangents ordinarily furnished on pipe bends do not add materially to the expansion value.

3. Bends made to a shorter radius than 5 or 6 diameters of the pipe have practically no expansion value, as they will buckle when bending.

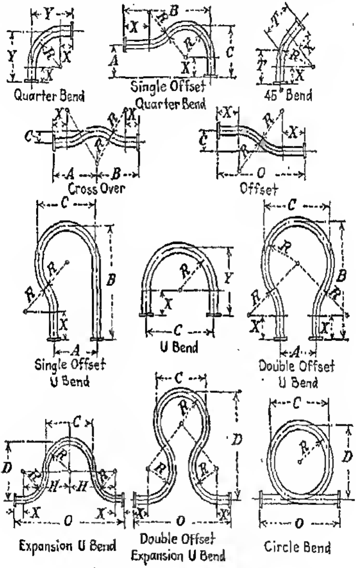

Fig. 6.—Various Types of Pipe Bends.

4. Bends are superior to the ordinary pipe-and-fitting structure because they are more flexible and do not throw all the load on the joints. Comparative tests showed that the built-up structure invariably leaked at the flanged joints, and in many cases before the fitting had been stressed near to the maximum allowable fiber stress.

5. A U bend has twice the expansion value of a 90 deg or quarter bend of the same size and radius, and an expansion U bend 4 times the expansion value of a quarter bend or twice that of a U bend. A double offset expansion U bend has 2½ times the expansion value of a U bend, and 1¼ times that of an expansion U bend.

Commercial sizes of **aluminum tubing** are listed by the manufacturers in even outside diameters and in wall thicknesses conforming to Stubs gage. **Aluminum pipe** is available in "standard" and "extra-heavy" iron pipe sizes. To obtain the approximate weight per foot of aluminum pipe or tubing, a weight of 0.098 lb per cu in. may be used.

Lead pipe is supplied in straight lengths, in coils, or in reels. The sizes and weights in Tables 24 to 26 are from the catalogue of the National Lead Co. The data in Table 25 conform to the standards advocated by the Lead Industries Assoc.

FITTINGS FOR WROUGHT-IRON AND STEEL PIPE

American Standard Cast-iron Pipe Flanges and Flanged Fittings

For Maximum Working Saturated Steam Pressure of 25 Lb, 125 Lb, and 250 Lb per Sq In. (Gage)

Sizes. The sizes of the fittings in the following tables are nominal pipe sizes. In the 25 lb standard, the nominal pipe size is the same as the port diameter of the fittings for *all* sizes. In the 125 and 250 lb standards the nominal pipe size is the same as the port diameter of fittings for pipe having inside diameters of 12 in. and smaller. For pipe 14 in. and larger, the corresponding outside diameter of the pipe is given, and consequently the fittings will have a smaller port diameter.

Pressure Rating. In the 25 lb standard, the sizes 36 in. and smaller may also be used for maximum non-shock working hydraulic pressures of 43 lb per sq. in. or a maximum gas pressure of 25 lb per sq in. at or near the ordinary range of air temperatures. In the 125 lb standard, the sizes 12 in. and smaller may also be used for maximum non-shock working hydraulic pressure of 175 lb per sq in. gage, at or near the ordinary range of air temperatures. In the 250 lb standard, the sizes 10 in. and smaller may also be used for maximum non-shock working hydraulic pressures of 325 lb per sq in. at a temperature of 250 F, and for maximum non-shock working hydraulic pressures of 400 lb per sq in. at or near the ordinary range of air temperatures.

The **physical requirements** of these flanges and fittings shall be as follows. Minimum tensile strength for light (medium) [heavy] castings 20,000 (21,000) [24,000] lb per sq in.; light castings are defined as those having any section less than 1/2 in. thick, heavy castings have no section less than 2 in. thick, and medium castings are in between. Sulphur content not to exceed 0.12 percent.

Facing. All 25 lb and 125 lb cast-iron flanges and flanged fittings shall be plain faced; *i.e.*, without projection or raised face. All 250 lb cast-iron flanges and flanged

See "Introductory Notes," p. 922.
[a] The stress shown is that of internal pressure only assumed to act on a circular area equal in diameter to the outside diameter (1) of the ring gasket covering the flange to the inside of the bolts for the 25 lb standard, and (2) of the raised face for the 250 lb standard.

fittings shall have a raised face 1/16 in. high, of the diameters given in Table 27. The raised face is included in the minimum flange thickness and center-to-face dimensions.

An inspection limit of ±1/32 in. shall be allowed on all center to contact surface dimensions for sizes up to and including 10 in. and ±1/16 in. on sizes larger than 10 in. An inspection limit of ±1/16 in. shall be allowed on all contact-surface to contact-surface dimensions for sizes up to and including 10 in. and ±1/8 in. on sizes larger than 10 in.

Dimensions. In the 25 lb standard, the flange diameters, bolt circles, and number of bolts are the same as in the 125 lb American Standard (A.S.A. B16a-1939), with a reduction in the thickness of flanges and bolt diameters, thereby maintaining interchangeability between the two standards.

The center-to-face and face-to-face dimensions of 25 lb standard fittings are the same as for the 125 lb standard.

Bolting. Drilling templates are in multiples of four, so that fittings may be made to face in any quarter. *Bolt holes shall straddle the center line. For bolts smaller than* 1 3/4 in., the bolt holes shall be drilled 1/8 in. larger in diameter than the nominal size of the bolt. Holes for bolts 1 3/4 in. and larger shall be drilled 1/4 in. larger than nominal diameter of holts. Bolts shall be of steel with standard "rough square heads" and the nuts shall be of steel with standard "rough hexagonal" dimensions; all as given

of thicknesses for outside diameters as follows: cold drawn; ¼ to 1½ in. by sixteenths, 1½ in. to 5½ in. by eighths, and 5¾ to 10¾ in. by quarters. Hot drawn; 6½ to 12 in. by halves, and 12 to 20 in. by inches. Some of these sizes, with their thicknesses and weights, are given in Table 20. Dimensions and weights of boiler tubes are given in Tables 21 and 22.

Spiral Pipe. Spiral pipe is strong lightweight steel pipe with a single continuous helical seam (riveted or welded) from end to end stiffening it throughout. The **spiral-riveted pipe** is listed in sizes 3 to 42 in. inside diameter, in various thicknesses, and in lengths up to 40 ft. It is used for high- and low-pressure water lines, vacuum lines, exhaust-steam lines, low-pressure air lines, sand and gravel conveying, and similar services. It is stronger than straight-riveted pipe of equal size. The **spiral-welded pipe** is listed in sizes 3 to 30 in. inside diameter, in various thicknesses, and in lengths up to 40 ft. In addition to the uses given above for spiral-riveted pipe, it is used extensively by the petroleum industry, for oil and gas lines, for low-pressure steam lines, etc.

Spiral pipe may be asphalt coated or galvanized. The pipe is designed for special joints, flanges, and lightweight fittings, but the American Standard flanges and fittings can be furnished, if desired. For further details, refer to catalogue of Taylor Forge and Pipe Works, Chicago.

(For weights, see Table 30.)

design of heads. Hexagonal nuts for pipe sizes 48 to 96 in. in the 125 lb standard and 18 to 48 in. in the 250 lb standard can be conveniently pulled up with box wrenches.

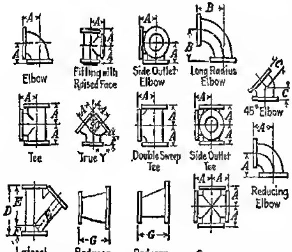

FIG. 8.—American Standard 25 Lb, 125 Lb, and 250 Lb Cast-iron Flanged Fittings. (25 Lb and 125 Lb Have Plain Face: 250 Lb Fittings Have $1/16$ In. Raised Face.) See Tables 28 to 34.

Thin brass tubing commonly used for ornamental work, brass hand railings, etc., is not of the proper size to take the standard pipe thread and is too thin for pressure work. Brass pipe is not liable to corrosion. The average ultimate strength is about 18,000 lb per sq in.

Copper pipe deteriorates rapidly under high temperatures and repeated stresses. At a temperature of 360 F, its strength is reduced 15 percent, and on this account it should never be used for high steam pressures and temperatures.

See notes at bottom of p. 931.

in the American Standard on Wrench Head Bolts and Nuts and Wrench Openings of the National Screw Thread Commission (see p. 767)." For bolts, 1¾ in. diam and larger, bolt-studs with a nut on each end are recommended.

Hexagonal nuts for pipe sizes 1 to 48 in. in the 125 lb standard and 1 to 16 in. in the *250 lb standard can be conveniently pulled up with open wrenches of minimum*

Table 28. General Dimensions of Flanged Fittings—Straight Sizes

American Standard

Bolting material including nuts and washers are based on a high-grade product equal to that given in A.S.T.M. Standard Specifications for Alloy-steel Bolting Material for High Temperature Service No. A96-33 and with physical and chemical requirements in accordance with the tables given under A.S.A. B16e-1939. Commercial steel bolts should not be used at steam pressures over 250 lb per sq in. and temperatures over 450 F. Nuts should be of carbon or alloy steel. Washers when used under nuts should be of forged or rolled carbon steel.

Table 32.* Steam, Water, and Oil Pressure Temperature Ratings for Carbon Steel Flanged Fittings and Companion Flanges
(Other-than ring joints)

Steam and water pressure rating (primary)	150	300	400	600	900	1500

950	55	165	220	330	495	825
1000	40	120	160	240	360	600

* For temperature ratings for 2,500 lb pressure, see A.S.A. B16e-1939.
All pressures are in pounds per square inch (gage).
[a] Primary service pressure rating.

Bolting. Drilling templates are in multiples of four, so that fittings may be made to face in any quarter. Bolt holes straddle the center lines. Bolt holes are drilled 1/8 in. larger in diameter than the nominal size of bolt. Bolts or bolt studs threaded at both ends may be used and shall be equipped with cold-punched or cold-pressed semifinished nuts of American Standard rough dimensions, chamfered and trimmed.

All bolts and bolt studs having diameters from 1/2 in. to and including 1 in. and the corresponding nuts shall be threaded with the American (National) Standard Screw

Spot Facing. The bolt holes of 25 lb, 125 lb and 250 lb cast-iron flanges and flanged fittings shall not be spot faced for ordinary service. When required, the flanges and fittings in sizes 36 in. and larger may be spot faced or back faced to the minimum thickness of flange with a plus tolerance of ⅛ in.

Reducing Fittings. Reducing elbows and side-outlet elbows carry same dimensions center to face as straight-size elbows corresponding to the size of the larger opening.

Tees, side-outlet tees, crosses, and laterals sizes 16 in. and smaller, reducing on the outlet or branch, have the same dimension center to face and face to face as straight-size fittings corresponding to the size of the larger opening. Sizes 18 in. and larger, reducing on the outlet or branch, are made in two lengths depending on the size of the outlet as given in the tables of dimensions.

Tees, crosses, and laterals, reducing on the run only, have the same dimensions center to face and face to face as straight-size fittings corresponding to the size of the larger opening.

Reducers and eccentric reducers for all reductions have the same face-to-face dimensions for the larger opening as given in Table 28.

Special double branch elbows whether straight or reducing have the same dimension center to face as straight size elbows corresponding to the size of the larger opening.

Side-outlet elbows and side-outlet tees shall have all openings on intersecting center lines.

Elbows. Special degree elbows ranging from 1 to 45 deg have the same center to face dimension given for 45 deg elbows, and those over 45 deg and up to 90 deg shall have the same center-to-face dimensions given for 90 deg elbows. The angle designation of an elbow is its deflection from straight line flow and is the angle between the flange faces.

Screwed Companion Flanges. Screwed companion flanges in the 25 lb standard shall not be thinner than those in the 125 lb standard on sizes 24 in. and smaller. Other types of flanges may have thicknesses as given in Table 27.

Table 29. General Dimensions Cast-iron Reducing Tees, Crosses, and Laterals

25 Lb, 125 Lb, and 250 Lb American Standard
(All dimensions in inches. Letters refer to Fig. 9)

* See introductory notes, p. 931.

True Y's. The dimensions of true Y's, straight sizes, are given in Table 28. Other forms are considered special and should be made to suit conditions.

Laterals. Laterals (Y branches) both straight and reducing sizes 8 in. and larger shall be reinforced to compensate for the inherent weakness in the casting design.

The American Standard covers also dimensions (not included in the Tables) of base elbows and base tees and anchorage bases for straight tees and reducing tees.

American standard cast-iron pipe flanges and flanged fittings (A.S.A. B16b1-1931) are available for maximum non-shock working hydraulic pressure of 800 lb per sq in. (gage) at ordinary air temperatures.

Sizes of Wrenches for Bolting Up Flanges. Tests made by Crane Co. (*Valve World*, Sept., 1913) show that a compression of about 12,000 lb can be obtained by one man using a 16 in. wrench on ¾ to 1 in. bolts, a 36 in. wrench on 1⅛ to 1⅜ in. bolts, a 60-in. wrench on 1½ to 1¾ in. bolts, and a 72 in. wrench on 1⅞ and 2 in. bolts. Square nuts give 20 to 25 percent less compression than hexagon nuts with a given effort on the wrench. Rough-cut or uneven threads reduce compression 10 to 15 percent. Lubrication of threads and bearing surfaces increases compression about 50 percent over that obtained with dry threads and surfaces. It is not necessary to overstrain bolts specified in the American Standard if proper wrenches are used, and almost impossible to overstrain bolts larger than 1 in. diam. The following over-all lengths of box wrenches are recommended (interpolate for intermediate sizes):

Size of bolt, in.	½	⅝	¾	⅞	1	1¼	1½	1¾	2	2¼
Length of wrench, in.	7¾	9⅞	11½	13¼	15	19	23	27	30⅛	34

American Standard Steel Pipe Flanges and Flanged Fittings

For Maximum Working Steam Pressure of 150, 300, 400, 600, 900, 1,500 and 2,500 Lb per Sq In. (Gage) at 750 F

Introductory Notes

Pressure Ratings and Tests. These standards shall be known as the "American 150, 300, 400, 600, 900, 1,500, and 2,500 lb Steel Flange Standards (A.S.A. B16e-1939)," said pressure designation being the recommended rating at a temperature such as given in Table 33. This table shows recommended ratings for various temperatures, together with hydrostatic shell test pressures for one set of conditions. For similar tables for other conditions, refer to A.S.A. B16e-1939.

Sizes. The size of the fittings and companion flanges in the Tables is identified by the corresponding nominal pipe size. For pipe 14 in. and larger, the corresponding outside diameter of the pipe is given.

Materials. The flanged fittings and flanges should be either steel castings or steel forgings of the grade complying with the A.S.T.M. specifications recommended under these standards for the various pressure-temperature ratings for which these standards are designed. A few of these characteristics selected from A.S.A. B16e-1939 are given in Table 33.

Notes to Table 31

[a] The weights of screwed companion flanges in the 25 lb standard, on sizes 24 in. and smaller may be assumed to be the same as in the 125 lb standard (see "Introductory Notes," p. 927).

[b] Also length of threads in 125 lb standard.

All 250 lb cast-iron standard flanges have a $\frac{1}{16}$ in. raised face. This raised face is included in the minimum thickness of flange dimensions. Sizes 14 in. and larger are to be used with outside diameter pipe of the same sizes.

All blind flanges for sizes 12 in. (19 in. O.D.) for 125 lb standard and 10 in. (17½ in. O.D.) for 250 lb standard and larger must be dished, with inside radius equal to the port diameter.

All weights listed are for flanges faced only, based upon minimum thicknesses given in the table above without allowances for variation.

Thread, Coarse Thread Series, Medium Fit, Class 3 (see p. 761). Bolts and bolt studs whose diameters are $1\frac{1}{8}$ in. and larger shall have special threads of the American (National) form whose pitch is $\frac{1}{8}$ in. (8 threads per in.). It is recommended that these special threads be allowed a pitch diameter tolerance of −0.006 in. and a lead tolerance of ±0.002 in.

Bolt studs with a nut at each end are recommended for high-temperature service.

Table 33. Physical Characteristics of Steels for Flanges and Fittings

	Steel castings[a]	Alloy-steel bolt material[b]			Forged-steel flanges[c]	
		Class A	Class B	Class C	Class I	Class II

Elongation in 2 in., min, percent	22	20	20	16	22	18
Reduction of area, min, percent	30	50	50	50	35	24

[a] Carbon steel (A.S.T.M. A95-36).
[b] (A.S.T.M. A96-33).
[c] (A.S.T.M. A181-37).
Phosphorus max., 0.05 percent; sulphur max. 0.05 percent.

The allowable working fiber stress, considering internal allowable working pressure only, in bolting material for valve bonnet flanges, cleanout flanges, etc., shall not exceed 9,000 lb per sq in. assuming the pressure to act upon an area circumscribed by the periphery of the outside of the contact surface.

All flanges shall be spot faced or back faced parallel to the flange face. Metal removed in spot facing or back facing shall not reduce the thickness of the flange below the minimum given in the tables. Spot facing does not apply to forged steel flanges if the back of the flange is parallel to the flange face.

Metal Thickness. Minimum metal thicknesses specified in the tables are based on an allowable fiber stress of 7,000 lb per sq in. using the modified Barlow formula of the A.S.M.E. Boiler Construction Code for cylindrical sections and adding 50 percent to the thickness thus determined to compensate for the shape of the fittings. The minimum commercial casting thickness is considered to be $\frac{1}{4}$ in., therefore the standards do not show thicknesses less than this. The minimum thickness in these standards means the minimum thickness in any part of the finished casting.

The modified Barlow formula is as follows: For pipes having nominal diameters of $\frac{1}{4}$ to 5 in., $P = 2S(t - 0.065)/D - 125$. For pipes of nominal diameters over 5 in., $P = 2S(t - 0.1)/D$, where P is the working pressure, lb per sq in.; t is the thickness of wall of pipe, in.; D is the actual outside diameter of pipe, in.; and S is 7,000 lb per sq in.

Ring Joints. The dimensions used for ring and groove joint facings were developed by a committee of the A.P.I. The corresponding dimensions and ring numbers incorporated in this standard (B16e-1939) are identical with those given in A.P.I. Std. No. 5-G-3-1937. The dimension for the depth of groove is added to the basic flange thickness which makes it necessary to include separate tables of dimensions for fittings having the ring joint facing.

Notes to Table 34

* Included in the minimum flange thickness dimensions. A $\frac{1}{16}$ in. raised face is also permitted on the 400, 600, 900, 1,500, and 2,500 lb flange standards, but it must be added to the minimum flange thicknesses. Regular facing for 400, 600, 900, 1,500, and 2,500 lb flange standards is a $\frac{1}{4}$ in. raised face not included in minimum flange thickness dimensions.

A tolerance of $\frac{1}{64}$ in. is allowed on the inside and outside diameters of all facings.

Gaskets for male-female and tongue-groove joints shall cover the bottom of the recess with minimum clearances taking into account the tolerances stated above.

union of the gasket type, at the center a female screw union having a brass to iron seat that is non-corrosive and a ground joint that eliminates the need for a gasket, and at the right a flange union of the gasket type. As in the case of other pipe fittings, unions and union fittings are available in the various pipe sizes and in materials and designs suitable for any service conditions.

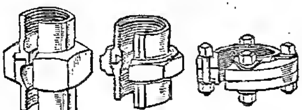

FIG. 11.—Types of Pipe Unions.

Very large flange unions can be made by bolting together two screwed companion flanges.

Expansion Joints for Steam Pipe Lines. The linear expansion of a long pipe must be taken care of by the use of some form of expansion joint or bend. The coefficients of expansion a of three metals used in pipe manufacture, within the range of temperatures common to boiler practice (32 to 392 F), as determined at the Bureau of Standards, Washington, D. C., are as follows: charcoal iron, 0.0000068S61; Bessemer steel, 0.0000069S0; seamless open-hearth steel (hot-finished), 0.0000068S3. The length of a tube at t F $= L_t = L\ (1 + at)$ in which L is the length of the tube at 0 F. See also p. 497. The theoretical expansion in 100 ft of iron or steel pipe, carrying steam of various pressures and temperatures, based on an outside temperature of 32 F, is as follows:

FIG. 12. FIG. 13. FIG. 14.
FIGS. 12-14.—Copper Expansion Joints for Steam Lines.

Steel and wrought iron	0.5	0.9	1.3	1.7	2.2	2.6	3.0	3.5	4.0	5.0	6.0
Cast iron	0.5	0.8	1.2	1.6	1.9	2.3	2.7	3.1	3.5		
Copper	0.8	1.4	2.0	2.5	3.1	3.7	4.3	4.9	5.6		
Brass and bronze	0.8	1.4	2.1	2.7	3.4	4.1	4.8	5.5	6.2		

Fitting Dimensions. An inspection limit of ±1/32 in. shall be allowed on all center-to-contact surface dimensions for sizes up to and including 10 in., and ±1/16 in. on sizes larger than 10 in. An inspection limit of ±1/16 in. shall be allowed on all contact-surface to contact-surface dimensions for sizes up to and including 10 in., and ±1/8 in., on sizes larger than 10 in.

When elbows having longer radii than specified in the standards are required, the use of pipe bends is recommended.

Laterals. The 45 deg laterals of the larger sizes may require additional reinforcement to compensate for the inherent weakness in this shape of casting.

Valve Dimensions. The center to contact surface and contact-surface to contact-surface dimensions of valves for the various pressures shall be in accordance with the proposed American Standard dimensions for ferrous flanged valves.

Reducing Fittings. Reducing fittings shall have the same center to flange edge dimensions as those of straight-size fittings of the largest opening.

Side Outlet Fittings. All side-outlet fittings shall have all openings on the intersecting center lines.

Welding Neck Flanges. The materials, facings, spot facings, etc., conform to the requirements given for other flanges, with the additional provision that the carbon content of the steel shall not exceed 0.35 percent.

Templates for drilling and center to contact surface dimensions of the American Standard 150 lb Steel Flanges and Flanged Fittings are the same as for the American Standard 125 lb Cast Iron Flanged Fitting Standard (Tables 27 to 29).

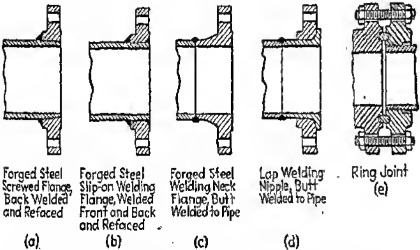

FIG. 10.—Welded Flange Joints and Ring Joint.

Templates for drilling and center to contact surface dimensions of the American Standard 300 lb Steel Flanges and Flanged Fittings are the same as for the American 600 lb Steel Flanged Fitting Standard for sizes 1/2 to 1 1/2 in. (Table 35); and the same as for the American 250 lb Cast Iron Flanged Fitting standard for sizes 2 to 24 in. (Tables 27 and 28).

Flanged Pipe Joints

The usual form of pipe joint is that made up by bolting together flanges cast or forged integral with the pipe or fitting, threaded flanges, loose flanges on pipes with lapped ends, and flanges arranged for welding. These forms are illustrated above Table 34 and in Fig. 10. The threaded joint is satisfactory for low and medium steam pressures. The lapped joint is permitted in the same sizes and service ratings as for joints with integral flanges. It is extensively used in high-class work. With the ring joint a higher pressure

malleable-iron screwed fittings of the American Standard are given in Tables 41 and 42.

The normal **amount of thread engagement** necessary to make a tight joint for American Standard Pipe Thread joints as recommended by Crane Co. is as follows:

Size of pipe, in.	1/8	1/4	3/8	1/2	3/4	1	1¼	1½	2
Length of thread, in.	1/4	3/8	3/8	1/2	9/16	11/16	11/16	11/16	3/4
Size of pipe, in.	2½	3	3½	4	5	6	8	10	12
Length of thread, in.	15/16	1	1 1/16	1 1/8	1¼	1 5/16	1 7/16	1⅝	1¾

* The complete standard (A.S.A. B16c-1939) covers also reducing couplings, elbows, tees, crosses and service or street elbows and tees.

The Manufacturers' Standardization Society of Valve and Fitting Industry (M.S.S.) has standardized **malleable-iron and bronze** screw fittings for several pressures.

Brass screwed fittings are made in both the 125 and 250 lb standards. They are used for feed-water pipes where bad water makes steel pipe undesirable. Brass fittings

[a] *The material of this standard (A.S.A. B16e2-1936) to be cast iron, malleable iron,* cast steel or forged steel, for use in connection with fittings covered by the American Standard 125 and 250 lb cast-iron screwed fittings (A.S.A. B16d) and the American Standard 150 lb malleable-iron screwed fittings (A.S.A. B16c).

Ammonia valves and fittings must provide a high margin of safety against accidents. Flanged valves and fittings have tongue and groove faces to assure tightness at the joints and against blowing out gaskets. Gaskets are of lead or compressed asbestos sheet. Screwed valves and fittings have long threads and are recessed so that the joints may be soldered. These valves and fittings are made of malleable iron, ferrosteel, or forged steel, depending on the size and style. Valves are all iron, with steel stems, and have special lead disk faces or steel disks. No copper or brass must be used in their construction. Flanged valves are generally interchangeable with flanged fittings. All valves and fittings for ammonia are tested to 300 lb air pressure under water. For dimensions of valves, fittings, and specialties for ammonia, refer to catalogue of Crane Co.

VALVES

Tables 45 to 48 give the dimensions and working pressures of representative valves suitable for steam lines. These types represent but a very small

can be maintained with the same **total bolt stress** than is possible with the flat gasket type of joint. The **welded joint** eliminates possibility of leakage between flange and pipe. It is very successful in lines subject to high temperatures and pressures and heavy expansion strains. The welding-neck flange is available in the various pipe sizes. Specific requirements covering the application of all the types of joints in common use are outlined in the Code for Pressure Piping (A.S.A. B31.1).

Facing of Flanges. Various styles of finish are used on the faces of flanges, having for their purpose the retention of the gasket used to make a tight joint. Those in general use are as follows: (see Table 34) plain straight face, plain face corrugated or scored, male and female, tongue and groove, and raised face. See pp. 897, 934.

The **plain straight face** has the entire face of the flange faced straight across and may be used with either a full face or ring gasket. The **plain face, serrated or V grooved,** is a plain face upon which concentric grooves have been cut with either a round-nose or V-shaped tool. This finish is sometimes of advantage when the service demands an exceptionally thick, loosely woven fibrous or soft metallic gasket, because the roughening of the faces of the flanges tends to keep the gasket from blowing out. The **male-and-female** facing consists of a recess in one flange and a corresponding raised face or projection on the other, extending from the inside of the pipe nearly to the inside of the bolt holes. In the **tongue-and-groove** facing, the tongue or raised face and the groove or recess are narrow rings located between the bolt holes and the port. The male-and-female and the tongue-and-groove facing have been extensively used, particularly on hydraulic lines, and to a more limited extent on high-pressure steam lines. Both of these types, however, have in common several objectionable features from the standpoint of manufacture, erection, and maintenance. These objections are removed by the use of the **raised-face** facing, which consists of a high narrow raised ring on each of the mating flanges, whose inside diameter is the same as that of the pipe or port. It is particularly recommended for high-pressure steam and hydraulic lines. Gaskets used in this type of joint are either soft fibrous material or soft metal and extend from the inside of the pipe to the bolt holes, and only the small portion in contact with the narrow raised face is subjected to the compressive effect of the bolts. The following advantages are claimed in the use of the raised-face type of facing: all mating of flanges eliminated; any valve or fitting may be removed from the line without springing the line apart; the gasket is automatically centered by its outer edge coming in contact with the bolts; the outside edges of the flanges are far enough apart to make it possible to determine whether the joint has been properly made.

The Bursting Pressure of Flanged Fittings. Results of hydraulic-pressure tests on flanged tees and ells made by Crane Co. (*Valve World*, Sept., 1913) are approximately expressed by the formula: bursting point, lb per sq in. $= tS/D$, where t = thickness of metal in the body of the fitting in in.; S = 65 percent of the tensile strength (T.S.) of the metal for fittings up to 12 in. diam (60 percent for larger diameters), and D = inside diam of fitting, in. A factor of safety of 4 to 8 should be used, depending on the size of the fitting. The formula is based on average of tests of 52 fittings made from cast iron (T.S. = 22,000) and "ferrosteel" (T.S. = 33,000).

Unions may be classified as **screw unions** and **flange unions.** Typical designs are shown in Fig. 11, where at the left is represented a female screw

service in locations where the projecting thread is not likely to be injured; inside screws should be used for underground work (as in water or gas pipes) or wherever the projecting spindle is liable to injury. **Brass bodies** are softer and will stand less abuse than iron or steel bodies. They should not ordinarily be used for sizes larger than 2 in. to 3 in. **Iron bodies** with brass mountings are recommended for larger sizes for water lines, steam and hot-water heating systems, and for saturated steam up to 250 lb pressure. For the higher steam pressures and temperatures, cast-steel valves are generally used. All-iron valves are recommended for oil or gas or for fluids that corrode brass.

Cocks. The ordinary plug cock operated by a handle or wrench is a form of valve in comparatively small sizes suitable for ordinary service only. The Code for Pressure Piping requires that where cocks are used for high-temperature service they shall be so designed as to prevent galling, either by making the plugs of different material from the body of the cock or by treating the plugs to ensure different physical properties. By means of special design features that eliminate the tendency to leak and stick, the plug-cock type of valve has become available in large sizes and for severe service conditions.

Figure 12 is a **corrugated copper expansion joint** for low pressures. Figure 13 shows a **globe-type joint** and Fig. 14 a **non-collapsible joint**, both of copper, and for low-pressure work. Face-to-face dimensions of some of these joints, compiled from manufacturers' catalogues, are given in Table 39.

The **rubber expansion joint** has become an established part of the pipeline equipment of the modern power plant. Its special field of application is on low-pressure and vacuum lines in condenser applications, etc., and is recommended for water pressure up to 25 lb, where the maximum temperature does not exceed 180 F. Sizes may be obtained up to 72 in. (see manufacturers' catalogues).

Screwed Fittings

Screwed fittings are made in **cast iron, malleable iron**, cast steel, forged steel, and brass. Plain standard **fittings** are generally used for low-pressure gas and water, as in house plumbing and railing work, while the beaded fitting is the standard steam, air, gas, or **oil fitting**. Screwed fittings are supplied with a large factor of safety. The **questions of strength** involve much more than the pressure from within the pipe which induces a comparatively low stress in the material. The greater **strains** come from expansion, contraction, weight of piping, settling, water hammer, etc. Dimensions of cast-iron and

* Approximate values.

with flange radiating area, gives lower first cost of piping under certain conditions, permits quicker delivery of pipe with welded outlets over that obtainable with special fittings, and reduces the cost of pipe covering, particularly in low-temperature work where cork insulation is used. The present tendency toward higher steam pressures and temperatures is leading to the elimination of as many gaskets as possible and to the sealing of steel flanges by welding.

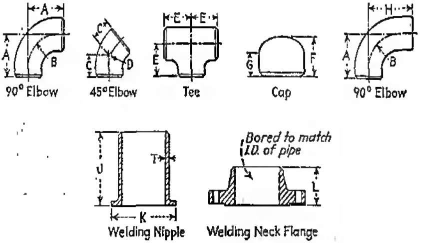

FIG. 17.—Fittings for Welding.

may be had in iron pipe sizes. Forged-steel screwed fittings are made for cold water or oil-working pressures up to 6,000 lb per sq in. hydrostatic. The A.S.A. has approved a standard (A.S.A. *A40.2-1936) for brass fittings for flared copper tubes for maximum* cold-water service pressure of 175 lb per sq in.

The 125 lb standard (A.S.A. B16d-1927) covers also reducing elbows and tees. The 250 lb standard (A.S.A. B16d-1927) covers only the straight sizes.

Railing Fittings. Fittings of special construction and of lighter weight than standard steam, gas, and water pipe fittings are widely used for hand railings around areaways, on stairs, for office enclosures with gates, and for permanent ladders. Railing fittings are made in various styles, generally globe-shaped in body, with ends reduced to take thread and recessed to cover all threads. They are furnished in malleable iron, black and galvanized, and in brass.

Special railing-fitting joints are available, such as the slip-and-screwed joint, where the post connection is screwed and the rim of the fitting is so made that the rail will slip into the fitting and allow for an angular variation of several degrees, being fastened by pins which are riveted over and filed smooth. The flush-joint stair-rail fitting is another special style of fitting which provides a hand rail with even surfaces at the joints.

Drainage fittings, as shown in the figures accompanying Table 44, have no pockets for the lodgment of solids, and the length of the thread chamber

Typical welded connections are shown in Fig. 10. In the back-welded screwed flange at (a), the threads retain the function of holding the flange securely in the pipe, hence, there is no shearing action on the weld. The fillet weld back of the flange forms a seal, assuring that no leakage will occur through the threads. The slip-on welding flange joint at (b) is limited by the Code to 300 lb pressure and a temperature of 700 F. The welding neck flange at (c) is machined with a beveled end and bored to match the thickness of the pipe. The welding nipple at (d) can be applied to piping cut to any desired length. Both the nipple and the pipe are machine beveled.

"Standard" and "extra-strong" fittings have the same outside dimensions. Welding nipples are furnished in the regular pipe sizes and wall thicknesses. The facing, drilling, thickness, etc., of welding neck flanges conform to the American Standards. For other welding fittings and other sizes, working pressure ratings at various temperatures, etc., refer to manufacturers' catalogues.

Pipe Supports

The code for Pressure Piping (A.S.A. B31.1-1935) includes many types of supports and gives directions for their application. A proper pipe support must have a strong rigid base properly supported, and an adjustable roll construction which will maintain the alignment in any direction. It is important to avoid friction caused by the movement of the pipe in the support and to have all parts of sufficient strength to maintain alignment at all times. Wire hangers, band iron hangers, wooden hangers, hangers made from small pipe and hangers having one vertical pipe support do not maintain alignment.

The direction of expansion in a pipe run can be predetermined by anchoring one end, both ends, or the middle. **Anchors** must be firmly fastened to a rigid and heavy part of the power plant structure, and must also be securely fastened to the pipe, otherwise, the equipment for absorbing expansion is useless, and severe stresses may be thrown on parts of the piping system. Some methods of support are shown in Figs. 18 to 20.

portion of the valves that are commercially available. Catalogues of manufacturers should be consulted for more detailed information.

* Other fittings which are available are as follows: 5⅝ deg, 11¼ deg, 22½ deg and 60 deg elbows; basin crosses; double 90 deg Y branches; double 90 deg long-turn Y branches; 45 deg double Y branches; S traps; half S traps; running traps; offsets.

† Other commercial sizes are 1, 10, 12, and 14 in.

According to the Code for Pressure Piping, valves for steam lines with pressures above 250 lb per sq in. but not over 1,500 lb and temperatures above 450 but not above 750 F should be of cast steel or forged steel. For pressures not over 250 lb and temperatures not over 450 F, they may be of cast iron, malleable iron, steel, or non-ferrous metal.

Several standards have been compiled and issued covering center-to-face dimensions of ferrous valves. The Manufacturers Standardization Society of the Valve and Fittings Industry issued SP-32 in 1937. The A.P.I. Standard No. 600A in 193[illegible] and No. 5-G-1 appeared in 1936 and the A.P.I. Standard No. 600A in 193[illegible] Dimension B in Tables 45 to 48 is in close agreement with the America[illegible] Standard "Face to Face Dimensions of Ferrous Flanged and Welding E[illegible] Valves" B16.10-1939, issued in 1939.

Selection of Valves. Gate valves reduce the frictional loss to a minimum [illegible] allow perfect drainage of the system. Outside screw valves are preferable for ind[illegible]

The distance between supports will vary with the kind of piping and number of valves and fittings. Supports should be provided near changes in direction, branch lines, and particularly near valves. The weight of piping should not be carried through valve bodies if they are to be kept tight.

In establishing the location of pipe supports, the designer should be guided by two requirements. (1) The horizontal span must not be so long that the sag in the pipe will impose an excessive stress in the pipe wall. (2) The pipe line must be pitched downward so that the outlet of each span is lower than the maximum sag in the span.

Tests conducted by Crane Co. to determine the deflection of horizontal standard pipe lines filled with water, in pipe sizes ¾ to 4 in., have indicated the following results: For pipes larger than 2 in. and with distance between supports greater than 10 ft, the resultant deflection is less than that determined by use of the formula for a uniformly loaded pipe fixed at both ends. For pipe sizes 2 in. and smaller, the test deflection was in excess of that determined by the formula for pipe having fixed ends and approached, for the shorter spans, the deflection as determined by the use of the formula for pipe having unrestrained ends.

Pipe Covering

(See p. 384 for heat-transmission data, and p. 715 for properties of insulating materials.)

The value of a steam-pipe covering is measured by the percentage reduction in condensation over that which occurs in bare pipe. This ranges from 65 to 85 percent, and even higher. The **standard covering** consists of 85 percent of carbonate of magnesia mixed with 15 percent of asbestos. The thickness of insulation necessary for most economical results under average conditions is shown in the following table.

Steam temperature, F		212–267	267–338	338–388	388–500	500–600
Thickness of insulation, in.	Pipes 4 in. and more	1	1½	2	2½	3
	Pipes 2 in. to 4 in.	1	1½	1½	2	2½
	Pipes ½ in. to 1½ in.	1	1	1	1½	2

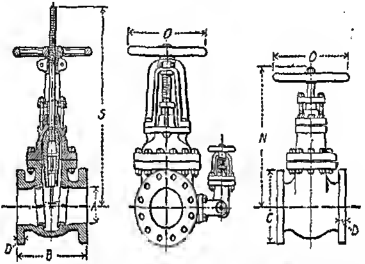
The covering is usually applied in molded sections (about 3 ft long) the seams of which are staggered and filled with magnesia plaster. Where the thickness of insulation is greater than 1½ in., it is desirable to apply it in two or more layers with joints broken or staggered. Fittings, valves, and flanges may be insulated with blocks and plastic material (plastic only on sizes smaller than 4 in.) to the same thickness as that of the adjacent pipe insulation. The sections are bound to the pipe by means of galvanized-iron wire or netting, over which is wrapped a coat of rosin-sized paper, followed by 8 oz canvas securely sewed on. **Asbestos air-cell covering** consists of several layers of corrugated asbestos sheets, making a laminated covering with air spaces between the corrugations.

A **wood casing** is sometimes used for underground steam or hot-water pipes, for exposed steam lines in mine shafts, etc., and for cold-storage and brine pipes. This covering is lined with tin for high-pressure steam lines, and is waterproofed for underground service.

L. B. McMillan (*Trans. A.S.M.E.*, 1915) finds, for coverings with white canvas surfaces, that the total heat flow in Btu per square foot of pipe surface per hour through a covering $= q_1 = Ut_d$, where U is taken from Table 52, and t_d = temperature difference, F, between pipe surface and air. The total Btu loss per hour per square foot of outside surface of covering $= q_2 = q_1r_1/(r_1 + s)$, where r_1 = outside radius of pipe, in., and s = thickness of covering, in. The temperature difference between the outer covering

Sizes are listed as high as 30 in. and are gear-operated in the larger sizes. For further details, refer to catalogue of the Merco-Nordstrom Valve Co., Pittsburgh, Pa.

Table 46. Dimensions of 175 Lb and 250 Lb Gate Valves
(Crane Co.)



(175 lb valves: ferrosteel body with brass trimmings, for steam working pressures, sizes 16 in. and smaller, up to 175 lb; for steam lines 18 in. and larger, 150 or 300 lb cast-steel gate valves are recommended. 250 lb valves: ferrosteel body with brass trimmings and hard metal seats; for steam working pressure up to 250 lb for steam lines 18 in. and larger, 300 lb cast-steel gate valves are recommended. All dimensions in inches. Letters refer to dimension sketches above. *For drilling templates, see Table 27.)*

Welding in Power-plant Piping

Welding is used as an economical or expedient method in making alterations and extensions to existing piping systems. It results in compactness, reduces the number of joints, minimizes radiation losses by doing away

Class	Color
F—Fire-protection equipment	Red
D—Dangerous materials	Yellow (or orange)
S—Safe materials	Green (or the achromatic colors, white, black, gray, or aluminum)
P—Protective materials	Bright blue
V—Extra valuable materials	Deep purple

Method of Identification. At conspicuous places throughout a piping system, color bands shall be painted on the pipes to designate to which one of the five main classes it belongs. If desired, the entire length of the piping system may be painted the main classification color.

Further, the actual contents of a piping system may be indicated by, preferably, a stenciled legend of standard size giving the name of the contents in full or abbreviated form. These legends shall be placed on the color bands. The identification scheme may be extended by the use of colored stripes placed at the edges of the colored bands.

The bands, legends, and stripes shall be placed at intervals throughout the piping system, preferably adjacent to valves and fittings to insure ready recognition during operation, repairs, and at times of emergency.

A recommended classification, under this color scheme of materials carried in pipes, includes as dangerous, combustible gases and oils, hot water and steam above atmospheric pressure; as safe, compressed air, cold water, and steam under vacuum.

Pressure Hose

Hose with durable rubber lining may be obtained to withstand any needed pressure. If the rubber compound is properly made, the life of a hose will be 7 to 10 years, while a cheaper hose, lined with inferior material, will probably not last more than 3 or 4 years. For fire hose, see p. 273.

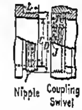

Fig. 21.—Typical Form of Standard Coupling.

American National Fire-hose Coupling Screw Thread. (Approved by the A.S.A., May, 1925, and indorsed and approved by the important engineering societies, and manufacturers and users of fire-hose couplings and hydrant outlets.) This standard is intended to cover the threaded part of fire-hose couplings, hydrant outlets, stand-pipe connections, and all other special fittings on fire lines, where fittings of the nominal diameters given in the following table are used. It also includes the limiting dimensions of the field inspection gages. The American National form of thread must be used.

Table 52. Dimensions of Standard Fire-hose Couplings
(All dimensions in inches. Letters refer to Fig. 23)

4½	5¾	4	1¼	7/16	1 3/16	⅜	1 5/16

American Standard Hose Coupling Screw Threads. (A.S.A. B33.1-1935) (approved by A.S.A., July, 1935). These standards apply to the threaded parts of hose couplings, valves, nozzles, and all other fittings used in direct connection with hose intended for fire protection or for domestic,

The use of welded branches, line welds, and swedges have made possible almost the entire elimination of fittings from steam headers, with a consequent decrease in cost. The line weld permits pipe to be joined up to the limit of shipping dimensions, which for single cars is two full lengths.

Cut pipe, bends, flanges, fittings, and valves with beveled edges can be obtained in the various sizes, suitable for welding assemblies. On welded headers, center-to-face dimensions of flanged nozzles always correspond to center to face of flanged tees of like series. Dimensions of welding neck flanges and welding fittings may be added without clearance at welded joints to obtain over-all dimensions. Typical welding fittings are shown in Fig. 17, and their dimensions are given in Table 49. See also A.S.A. B16.9.

[b] Approximate values.

The Code for Pressure Piping (A.S.A. B31.1-1935) outlines specific requirements concerning the welding of pipe joints by the fusion process and relates to such joints as are formed by pipe end to end, pipe to flanges, fittings and valves, and pipe, valve, or fitting to other equipment. It covers materials, types of welds, welding procedure, stress relief, qualification of welders, the testing of welded joints, etc.

WIRE ROPE, NAILS, ETC.*

Wire Rope

Wire ropes are built up of **strands** made of wires twisted together, the numbers of wires commonly used being 4, 7, 12, 19, and 37. Ordinarily the wires are twisted into strands in the opposite direction to the twist of the strands into rope. When wires and strands are twisted in the same direction, the rope is known as **lang lay rope.** **Standard wire rope** is made of six wire strands and a hemp core. Wire strands are twisted around the core, either to the right or left, and the resulting rope is thereby designated as right lay or left lay. The twist may be long or short, the shorter twist forming the more flexible rope. The **core** of a wire rope is, as a rule, hemp saturated with a lubricant. It provides little additional strength, but acts as a cushion to preserve the shape of the rope and helps to lubricate the wires. A wire strand or wire rope core adds 7 to 10 percent to the strength of the rope, but will wear from the friction between it and the outer strands as rapidly as the outside of the rope. This does not apply to stationary ropes.

For great flexibility, the strands of a wire rope sometimes consist of wire ropes, which in turn are made of strands composed of wires, as in tiller rope. Running ropes and one construction of ship's hawsers are made with strands composed of 12 or 18 wires each, twisted about a hemp center. Ropes so made are very pliable and present good resistance to outside friction. Individual strands of wires are employed as smokestack guys, span wires for trolley roads, and wherever only moderate flexibility is needed.

Strength and Working Loads. The test strength of wire ropes seldom exceeds 90 percent of the aggregate strength of all of the wires, the average being about 82.5 percent.

The working load should never exceed 1/5 of the breaking strength and for many conditions should not be greater than 1/8 to 1/6. The proper factor of safety for a wire rope demands consideration of all loads; acceleration; deceleration; rope speed; rope attachments; the number, size, and arrangements of sheaves and drums; conditions producing corrosion and abrasion; length of rope; etc. The desirable factor of safety for given conditions can best be obtained by consulting the manufacturers of the wire rope.

Sizes of Drums or Sheaves. (See also page 833.) Tread diameters for 6 × 7 (6 × 19) [6 × 37] {8 × 19} rope should be approximately 72 (45) [27] {31} times the rope diameters, for average conditions. For economical service, these should often be increased. For example, on larger hoisting installations with the 6 × 7 (6 × 19) rope, the diameters may be 96 (90) times the rope diameter. In certain cases, the tread diameters may be less but should not be below 42 (30) [18] {21} times the rope diameters. Larger tread diameters give increased rope life and more economical service.

The size and condition of the sheave grooves is most important in determining rope life. The clearances for new or remachined grooves and the minimum clearances before sheave replacement or remachining grooves, should be as follows:

Normal rope diam, in.	1/4–5/16	3/8–1 1/4	1 3/8–1 5/8	1 3/4–2 1/4
New clearances, in.	1/32	1/16	1/8	1/8
Min clearances, in.	3/64	1/32	1/32	3/64

If a wire rope is operated over grooves that are too small, the rope will be abraded rapidly; in addition, a tight or corrugated sheave groove may

* Staff contribution.

Table 50 gives dimensions that may be used for cast-iron rolls and stands for pipe supports. Figure 19 shows a heavy wall bracket adapted for any size of pipe 5 to 20 in. diam. Dimensions: *A*, 15 to 19 in.; *B*, 8 in.; *C*, 18¾ in.; *D*, 27 in. The universal adjustable bracket shown in Fig. 20 is made for pipe 5 to 14 in. diam. The inside dimension *A* ranges in six sizes from 6 in. to 21 in.; the range of adjustment outward in each size is 3 in., and any adjustment *A* between 6 and 24 in. can be obtained from some one of the sizes made.

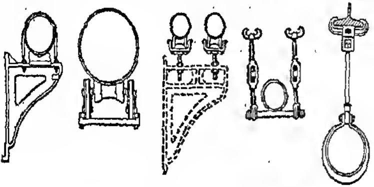

Fig. 18.—Methods of Supporting Pipes.

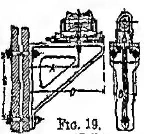

Fig. 19.

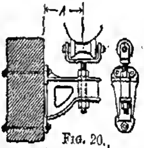

Fig. 20.

Wall Brackets for Supporting Pipes.

These rolls may also be adjustably mounted in various types of stands and hangers. Spring supports are recommended when vibration is present or when automatic adjustment for slight movement is necessary, in order to dampen the vibration and avoid line strains.

the abrasion which accompanies rapid hoisting. The wire in cast-steel rope has nearly twice the strength of that in Swedish iron rope and also has a much higher elastic limit. **Extra strong cast-steel rope** occupies an intermediate place between cast-steel and plow-steel rope. It is used in place of cast steel when it is desirable to increase the factor of safety for a given diameter. It may be used to advantage for general hoisting. **Plow-steel rope** is made of wire of great strength and toughness, capable of resisting severe abrasion. It can be used in place of cast-steel rope where it is desirable to reduce the dead weight of the rope itself, or where, by reason of increased loads, it is necessary to use a much stronger rope without increasing its diameter. Plow-steel rope is recommended especially for logging lines, scraper, dredge, and wrecking ropes, heavy cranes, ballast unloader ropes, and for all rough uses requiring maximum strength and toughness. **Improved plow-steel rope** is a special rope for extreme conditions. It has a maximum strength, toughness, and uniformity.

Standard hoisting rope (Fig. 1) is made of 6 strands, each of 19 wires, the strands being twisted around a hemp center.

For a temperature difference of 350 F.

he heat loss through any thickness of any material of which k is vn for $t_d \leqq 500$ F, is $q_2 = k(t_1 - t_2 - T_d)/[r_2(\log_e r_2 - \log_e r_1)]$, where t_1 t_2 are the temperatures of the pipe surface and room, respectively, F. he heat loss from bare pipe per degree temperature difference per hour square foot is as follows:

p. diff., F.	50	100	200	300	400	500
in Btu (= b)	1.95	2.152	2.665	3.26	4.035	5.18

he Btu saving due to covering per degree temperature difference per re foot per hour = $b - U$ (values of U in table), and the efficiency of covering in percent = $100(b - U)/b$. Thus, for the first covering in the ole, the saving per year per square foot of covering for a temperature ference of 300 F (for continuous operation, or 8,760 hr) = (3.26 − 0.413) 300 × 8760 = 7,482,000 Btu, and the efficiency = 100(3.26 − 0.413)/ 26 = 87.3 percent.

Identification of Piping

The A.S.A. has approved (1928) a **Scheme for the Identification of Piping** stems (A.S.A. A13-1928). This scheme is limited to the identification of piping stems in industrial plants, not including pipes buried in the ground, and electric conits. Fittings, valves, and pipe coverings are included, but not supports, brackets, or ner accessories.

Classification by Color. All piping systems are classified by the nature of the aterial carried. Each piping system is placed, by the nature of its contents, in the lowing classifications:

rope and requires larger sheaves. On account of the smaller number of wires, this rope should also be used with a higher factor of safety, as the breaking of one or two wires materially reduces the strength of the rope. The wires used are considerably larger in diameter than in hoisting rope, and consequently will stand greater wear. **Iron rope** of this construction is recommended for power transmissions equipped with large sheaves. **Cast-steel and extra strong cast-steel rope** are recommended for mine haulages, tramways, sand lines, and similar service where conditions tend to severe abrasion. **Plow-steel and improved plow-steel ropes** are recommended in place of cast steel when it is desirable to reduce the dead weight of the rope itself, or where, by reason of increased loads, it is necessary to use a stronger rope without increasing its diameter. This rope is particularly adapted for very long mine haulages.

Flat rope is composed of a number of wire ropes called "flat rope strands," of alternate right and left lay, placed side by side, then secured or sewed

together with soft Swedish iron or steel wire (Fig. 5). The flat-rope strands consist of four 7-wire strands laid together with a center or core. The sewing or filling wire is much softer than the steel wires composing the strands of the rope, acts as a cushion or soft bed for the strands, and wears out much faster than the harder wires composing the latter. When the sewing wires are worn out, the flat rope can be resewed with new wire, and if any of the rope strands are also worn or damaged, these can be replaced by new por-

Soldered-joint Fittings. The proposed American standard for these fittings (A.S.A. A40-) covers certain dimensions of soldered-joint wrought metal and cast brass fittings for copper tubing including (1) detailed dimensions of the bore, (2) minimum specifications for materials, (3) minimum inside diameter of the fitting, (4) metal thickness for both wrought metal and cast brass fittings, and (5) general dimensions for cast brass fittings including center-to-shoulder dimensions for both straight and reducing cast fittings. Pressure and temperature ratings also are given. Sizes of the fittings are identified by the nominal tubing size as covered by the American standard specifications for copper water tube, A.S.A. H23.1-1934 (A.S.T.M. B88-33).

Flattened-strand rope has little tendency to kink, and, owing to its smooth wearing surface, saves wear on pulleys, sheaves, and drums. It is made in the forms shown in Fig. 6. They are used for elevators, hoisting, dredging, etc. *For Type A, the minimum sheave size generally* recommended is 24 times the rope diameter, and the average, 36 times. For Type B, the corresponding values are 30 diameters minimum and 45 diameters average.

Non-spinning hoisting rope (Fig. 7) is constructed of 6 strands of 7 wires each, lang lay (wires in the strands and strands themselves twisted to the left) laid around a hemp core and covered with an outer layer composed of 12 strands, 7 wires, regular lay (wires in the strands twisted to the left and strands themselves twisted to the right). The object of this combination of lays is to prevent a free load suspended on the end of a single line from rotating. This type of rope is recommended for "back-haul" or single-line derricks; also for shaft sinking and mine hoisting where the bucket or cage swings free without guides. It works best where it does not overwind on the drum.

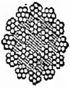

Fig. 7.

Either a closed or an open socket makes the best fastening on the end of non-spinning rope. These may be fastened in the same manner as any rope socket, but great care must be taken in attaching the socket to the rope to see that the strands do not untwist or allow any slack to work back into the rope. It is best to seize the end of the rope tightly for a distance of 4 or 5 in. just outside of the socket until the socketing is completed, when it may be taken off.

Steel-clad ropes (Fig. 8) are made in three constructions for the purpose of securing different degrees of flexibility: the 6 × 19, 6 × 37, and 6 × 61 types, respectively. Flat strips of steel wound spirally around each of the six strands composing the rope give additional wearing surface without sacrificing flexibility. When the outer flat-steel winding is worn through, a complete hoisting rope remains, with unimpaired strength. These ropes are designed to meet very severe conditions of service. The increased

disturb the strand relationship of the rope and necessitate its premature removal. The pressure of wire rope against a sheave groove is calculated by dividing the rope tension in pounds by the product of the radius to the bottom of the sheave groove and the diameter of the rope, both in inches. This quantity should not have a value greater than 450 lb per sq in. for cast iron, or 850 lb for cast steel. For greater pressures, a material of greater wear resistance, such as manganese steel, should be used.

Handling. Wire rope must not be coiled or uncoiled like hemp rope. When it is received upon a reel, the latter should be mounted upon a spindle or turntable and the rope then run off. When shipped in a coil, it should be rolled along the ground like a wheel. All untwisting and kinking must be avoided. When a wire rope is to be cut, soft iron wire should be served on each side of the place where the division is to be made to keep the rope from untwisting.

Materials. Rope made from **iron** wire is soft, tough, and pliable and has but little tendency to wear grooves in sheaves. This is of considerable advantage when wire rope is run over multiple-grooved sheaves. It is especially adapted for passenger elevators and similar service where the tendency to abrasion is comparatively slight, the speed is high, loads moderate. **Cast-steel rope** is recommended for general hoisting, such as mine hoists, derricks, coal hoists, cableways, conveyors, freight elevators, etc. It is tough and pliable, will bend over comparatively small sheaves and resist

Table 1. Standard Hoisting Rope

Composed of 6 strands and a hemp center, 19 wires to the strand

Galvanized mast-arm rope is used for arc lights, mast arms, or other purposes where exposed to moisture. This rope is more durable than manila rope and does not shrink.

Extra Pliable Hoisting Rope. Made of 6 strands of 37 wires each and a hemp center (Fig. 2). The wires in this rope are much finer than those used in the standard hoisting rope and consequently not as suitable to withstand abrasion. These ropes are used on electric cranes, dredges, and for similar service requiring a strong tough rope that will operate successfully over small sheaves.

Extra pliable hoisting rope of 8 strands of 19 wires and a hemp center (Fig. 3) is much more pliable than the standard construction of 6 strands of 19 wires. The metallic area of an eight-strand rope is not so great as that of a six-strand rope, and the wires are smaller, but under severe bending stresses the decrease in strength is largely offset by the great pliability. It can be used over comparatively small sheaves and drums such as are frequently found on derricks. It is not good practice to use it except for

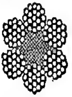

Fig. 1.

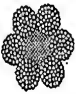

Fig. 2.

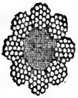

Fig. 3.

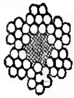

Fig. 4.

comparatively light loads or where there is much overwinding, because it would flatten or lose shape more quickly than 6×19 rope. Moreover it stretches more than a 6×19 rope.

Galvanized extra-pliable cast-steel hoisting rope is much more flexible than the six-strand hoisting rope, and is often used in preference to galvanized cast-steel running rope.

Standard coarse-laid rope (Fig. 4) is made of six strands and a hemp center, seven wires to the strand. It is much stiffer than standard hoisting

tions. Flat rope is used principally for hoisting purposes. When large and long rope is used in hoisting heavy loads out of deep shafts, round rope requires large and heavy drums on which to wind, while flat rope, winding on itself, needs a reel but little wider than the width of the rope. Furthermore, flat rope does not spin or twist in the shaft. Flat rope is obtainable from 1¼ to 8 in. in width, and from ¼ to ⅞ in. in thickness, the length varying from 20 to 3,000 ft. Flat rope is particularly applicable to the operating of spouts on coal and ore docks, also for raising and lowering emergency gates on canals and similar machinery. It combines flexibility and great strength, thus making possible the use of simple and compact hoisting machinery.

The diameters of **drums and sheaves** for flat rope should be as large as possible, particularly for mine hoisting work. For average continuous duty of 4 × 7 flat rope, *i.e.*, 4 strands with 7 wires to the strand, sheaves (drums) should be at least 96 (80) times the nominal thickness of the rope for intermittent duty such as flood gate hoists 60 (48): for shaft hoists with long lengths of rope, best economy requires about 200 (120).

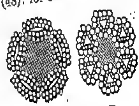
2¾	13.6	323.	.....	257.	233.

Sheaves should be slightly crowned in the center and have deep flanges to guide the rope.

Flattened-strand wire rope is designed to give increased contact or wearing surface. The wear is consequently lessened upon any one individual wire and the necessity of the use of heavier wire diminished, which results in greater flexibility. The wearing surface is approximately 150 percent greater than that of a round-strand rope. Another feature of this type of rope is that the interstices between the strands being lessened, a greater number of wires are used for the same diameter. It is always made lang lay.



A. B.

Fig. 6.

Nails and Spikes

Nails are either **wire nails** of circular cross section and constant diameter, or **cut nails** of rectangular cross section with taper from head to point. The larger sizes are called **spikes**. The length of the nail is expressed in the "penny" *system*, the equivalents in inches being given in the following tables; the letter "d" is the accepted symbol for penny. A keg of nails weighs 100 lb.

life obtained by the use of steel-clad rope is, in places where conditions are suitable, from 50 to 100 percent. It is recommended particularly for such service as dredging. The breaking strength of these ropes is less than that of a round strand rope of the same diameter and grade.

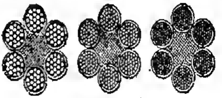

Fig. 8.—Steel-clad Ropes.

Galvanized wire rope has almost entirely superseded manila rope for shrouds and stays aboard ship. It is cheaper in first cost, is not affected by the weather, and does not stretch and contract with changes in atmospheric conditions, and thus saves a great deal of labor in setting up; it is as elastic as manila rope. There is great reduction in bulk and weight by its use, as it is only one-fifth or one-sixth as large as a manila rope of equal strength. Consequently, it offers only half as much surface to the wind. It is much less liable to accidents by being cut or chafed, and does not rot and give way suddenly without warning. Galvanized rope is better suited for guys for derricks than hemp rope or rods linked together.

Galvanized steel wire strand (Fig. 9) is used chiefly for guying poles and smokestacks, for supporting trolley wire, and for operating railroad signals. For overhead catenary construction of suspending trolley wire, the special grades of strand are preferable because they possess greater strength and toughness. The smallest sizes (sometimes called "galvanized seizing strand") are used for seizing or binding the ends of wire rope and thimble splices, and for tying rope into coils.

Fig. 9.

Wire Rope Fittings. When wire rope has to be cut to make attachment to fittings or for splicing, it is important that it should be properly seized: the wires and strands are twisted under uniform tension and this tension should be maintained. Three sets of seizings should be placed on each side of the cut with about 10 wraps of wire per seizing. Annealed iron wire should be used of the following diameters:

Rope diam, in.	3/8 and 1/2	5/8	3/4	7/8 and 1	1 1/8–1 7/8	2 and over
Seizing wire diam, in.	0.047	0.054	0.063	0.080	0.105	0.135

Attachment to a socket is made by separating and straightening the wires, cutting out the hemp center, cleansing with kerosine, dipping in one-half muriatic acid and one-half water, distributing the wires uniformly in the socket, and pouring in molten zinc after plugging up the lower end of the socket with fire clay; such an attachment will develop the full strength of the rope. Spliced eye connections when properly made will not pull out and will develop from 60 percent of the full strength of a 2 1/2 in. diameter rope up to 95 percent for a 1/2 in. rope. Clip and clamp connections are not desirable as permanent fastenings on hoisting ropes and will develop 75 to 85 percent of the strength of the rope.

Galvanized Common Steel Wire Strand

Knots, Hitches, and Bends

No two parts of a knot which would move in the same direction if the rope were to slip should lie alongside of and touching each other. The knots shown in Fig. 13 are known by the following names:

A, bight of a rope; B, simple or overhand knot; C, figure 8 knot; D, double knot; E, boat knot; F, bowline, first step; G, bowline, second step; H, bowline, completed; I, square or reef knot; J, sheet bend or weaver's knot; K, sheet bend with a toggle; L, carrick bend; M, "stevedore" knot completed; N, "stevedore" knot commenced; O, slip knot; P, Flemish loop; Q, chain knot with toggle; R, half hitch; S, timber hitch; T, clove hitch; U, rolling hitch; V, timber hitch and half hitch; W, blackwall hitch; X, fisherman's bend; Y, round turn and half hitch; Z, wall knot commenced; AA, wall knot completed; BB, wall knot crown commenced; CC, wall knot crown completed.

The bowline G, one of the most useful knots, will not slip, and after being strained is easily untied. Knots H, K, and M are easily untied after being under strain. The knot M is useful when the rope passes through an eye

Recommended Standard Cross Sections

The A.S.A. Tentative Standard, Z.14.1-1935, for representing section lining and outside views is shown in Figs. 14 and 15. Subdivisions of any of the materials may be made by taking one of these standard cross sections as a basis and making minor changes or by writing on the standard cross section the name of the material.

Tramway strand (see below) has usually 19, 32, 37, 61, or 91 wires, according to the diameter of the strand and the conditions of its use. It is recommended for the track or trolley cable on an aerial tramway on account of its compact construction, and is found, by reason of its comparatively smooth surface, to reduce greatly the friction on the carriage wheels. In long spans where the weight of the rope itself is a disadvantage, plow-steel quality is generally used.

and is held by the knot, as it will not slip, and is easily untied after being strained. The wall knot is made as follows: Form a bight with strand 1 and pass the strand 2 around the end of it, and the strand 3 around the end of 2, and then through the bight of 1, as shown at Z in the figure. Haul the ends taut when the appearance is as shown at AA. The end of the strand 1 is now laid over the center of the knot, strand 2 laid over 1, and 3 over 2, when

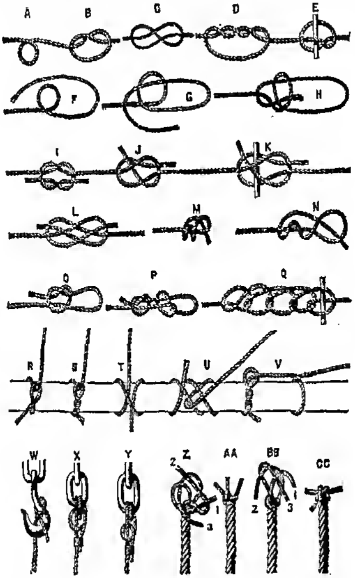

Fig. 13.—Rope Knots, Hitches, and Bends.
(From C. W. Hunt Co.'s Catalog)

the end of 3 is passed through the bight of 1, as shown at BB. Haul all the strands taut, as shown at CC. The "stevedore" knot (M, N) is used to hold the end of a rope from passing through a hole. When the rope is strained, the knot draws up tight, but it can be easily untied when the strain is removed. If a knot or hitch of any kind is tied in a rope, its failure under stress is sure to occur at that place. The shorter the bend in the standing rope, the weaker is the knot. The approximate strength of knots compared

PREFERRED NUMBERS

By C. H. BERRY

Mach.*, July 12, 1923; Tornebohm, "The Development and Importance of Preferred Number Series," *Mech. Eng.*, Oct., 1923; Schlink, "Use of Preferred Numbers," *Jour. S.A.E.*, Feb., 1925; "Table of Preferred Numbers," *A.S.A. Standard* Z17.1-1936; Steczynski, "Preferred Numbers for American Practice," *Mech. Eng.*, Nov., 1928; von Dobbeler, "Preferred Numbers," *Mech. Eng.*, March, 1929.

Many manufactured articles are made in several sizes which may be designated by some dimension, speed, capacity, or other feature. Each such series of products may be paralleled by a series of numbers.

It is generally agreed that such number series should be **geometric progressions**, *i.e.*, each term should be a fixed percentage larger than the preceding. A geometric series provides small steps for small numbers, large steps for large numbers, and this best meets most requirements. The small steps in the diameter of the numbered twist drills would be absurd in drills of 1 in. diameter and larger.

In the case of sized objects that are used principally as raw material, *e.g.*, steel rod, an arithmetic progression may be preferable because it tends to reduce the cost of machining. It is desirable to be able to buy raw material a fixed amount (rather than a fixed percentage) larger than the finished article.

Preferred numbers is the name given to various series proposed for general use. These are either geometric progressions or approximations thereto. A geometric series is defined by one term and the ratio of each term to the preceding. On the choice of these elements for a preferred number series, there is as yet no general agreement. The same value would hardly be satisfactory for all cases. The idea of preferred numbers is to provide a master series from which terms can be chosen to suit any needs. This would ultimately lead to a comprehensive plan in all fields of manufacture, so that, for example, the sizes of shafting would be in accord with the sizes of bearings, and indeed with all manner of cylindrical machine elements.

An advantage of a geometric series is that if linear dimensions are chosen in the series, areas and volumes and other functions of powers of dimensions are also members of the same series.

In one of the most carefully considered systems of preferred numbers the base term is 1, and the ratio is $\sqrt[80]{10}$. In this series, the 81st term is 10, and accordingly the series from 10 to 100 or from 0.01 to 0.1, or, in general, from 10^n to 10^{n+1} is identical with the series from 1 to 10 with the decimal point shifted. This series will rarely be used in full; some will choose alternate terms, some every fourth, fifth, tenth, or twentieth term. The index of the root, 80, has as factors 2^4 and 5, so that the series readily yields sub-series having as ratios the roots of 10 with indices 2, 4, 8, 16, 5, 10, 20, 40, thus giving a wide range of choice.

The strict logic of this series has been somewhat impaired by the adoption of rounded values that are slightly different in the 1 to 10 and 10 to 100 intervals. For the United States, the A.S.A. has adopted a Table of Preferred Numbers (A.S.A. Z17.1-1936) which differs slightly from the system described in the preceding paragraph.

Another type of series is the **semigeometric** series (Steczynski, *loc. cit.*) consisting of a basic geometric series with 1 as the base term, and a ratio of 2, giving a series . . . $\frac{1}{8}$, $\frac{1}{4}$, $\frac{1}{2}$, 1, 2, 4 . . . . Between consecutive terms are inserted arithmetic series of 2, 4, 8, or 16 terms, in general using different numbers of terms in different intervals.
